The algebra involved is actually not much more difficult than the more conventional techniques which the next chapter uses, but a complete explanation of it is somewhat beyond the scope of this book. Should you already be familiar with it then Appendix 4 gives a quick restatement of its principle techniques.

Even if you are not (or don't want to bother with it) its not really a problem. There are some simple rules and special cases of phasor mathematics which are presented below. In Part Three we will consider what some basic circuits do under these conditions and hence get a lot of insight into their workings. You could take these ideas on board now, or refer back to this point when you get there. Anyway, here goes:

Phase Rule 1:	For waveforms in phase, magnitudes of quantities can be used in calculations directly. The phase of the result is the same as that of the 'inputs' to the calculation.
Phase Rule 2:	A positive value of phase means 'leading', a negative one 'lagging'.
Phase Rule 3:	A negative value of magnitude means an inversion of the quantity

(i.e. it is in antiphase). So subtraction is addition with one waveform inverted. We could say that $-V$ is V at an angle of 180°.

Phase Rule 4: Adding two equal waveforms in antiphase gives a result of zero. This is called 'phase cancellation'.

Phase Rule 5: Multiplication of any pair of waveforms. The magnitudes are multiplied and the phase angles added together.

Phase Rule 6: Division of any pair of waveforms. The magnitudes are divided and the phase of the denominator subtracted from the phase of the numerator.

Resistors and sine waves

The terms pk, pk–pk and RMS can be used to refer to both voltages and currents. Provided that we are consistent we can do Ohm's Law calculations on resistors with any of them. So, for example:

1. A pk voltage of 10 V across a 1k resistor causes a pk current of $\frac{10}{1000} = 10\,\mathrm{mA}$ to flow.
2. A pk–pk current of 3 mA through a 4k7 resistor causes a pk–pk voltage of $3 \times 4\mathrm{k}7 = 14.1\,\mathrm{V}$ across it.
3. An RMS voltage of 150 V across a 1M resistor causes an RMS current of $\frac{150}{1\mathrm{M}} = 150\,\mu\mathrm{A}$ to flow.

Current and voltage through a resistor are always in phase. In fact, the current waveform is always an exact replica of the voltage waveform, its magnitude at every point being determined by Ohm's Law.

Capacitors and sine waves

A capacitor with a sinusoidal voltage of frequency f across it will have a sinusoidal current flowing through it. The ratio of the voltage to the current is known as the 'reactance' of the capacitor at frequency f. The situation is analogous to that with a resistor, and the unit of reactance is again ohms. And Ohm's Law again applies:

$$V_C = I_C X_C \tag{4.5}$$

where X_C is capacitive reactance, V_C is the voltage across the capacitor and I_C is the current through it. As with resistors, amplitudes of voltage and current can be specified using pk, pk–pk or RMS conventions, so long as the same is used for both.

We can calculate the reactance of a capacitor at any particular frequency using the expression:

$$X_C = \frac{1}{2\pi fC} \tag{4.6}$$

where C is the capacitance in farads and f is the frequency. We can see from this that the magnitude of the reactance of a capacitor decreases proportionally with frequency.

But hold on! Capacitors are more than 'frequency-dependent resistors'. They do something important to AC signals. The current through a capacitor always leads the voltage across it by 90°. This is the difference between a capacitor and a resistance with the same value as its reactance at that frequency.

We can often get a very good idea of what a circuit does by thinking of caps as 'frequency-dependent resistors', but we can't do calculations to solve CR networks (using techniques from Chapter 5) without taking account of phase. (A CR network is any consisting of capacitors and resistors – we'll meet CR, LR and LCR networks in Part Two.)

For calculation purposes, we consider that capacitive reactance has a phase angle of −90°, as passing a current with a phase angle of 0° through it results in a voltage of 90° lagging. (See Phase Rules 5 and 6 earlier in this chapter.) (It is this idea of assigning phase to reactance that makes otherwise incomprehensible complex numbers work.)

Now that we've met the terms resistance and reactance, this seems like the moment to mention the word 'impedance', which is used a lot. Strictly speaking, resistors have resistance, capacitors (and inductors) have reactance. Circuits have some combination of the two. If you want to be non-committal about which you mean, say 'impedance' – it can be either. And everyone should understand.

Inductors and sine waves

Like capacitors, the sinusoidal voltage across and current through an inductor are proportional at any given frequency. The ratio is again known as the reactance of the inductor, and here's Ohm's Law again:

$$V_L = I_L X_L \tag{4.7}$$

with X_L as inductive reactance, V_L voltage across the inductor and I_L current through it. Again we may use pk, pk–pk or RMS amplitudes but must be consistent. For an inductor voltage leads current by 90°, so we consider that the reactance has a phase angle of 90°. The inductive reactance can be calculated using the expression:

$$X_L = 2\pi fL \tag{4.8}$$

where L is the inductance in henries and f is the frequency in hertz. From this, inductive reactance increases proportionally with frequency.

(Again we see capacitors and inductors doing nice complementary things to each other, while resistors form a nice 'neutral background' against which to view it all.)

Why are sine waves so important?

In other words, why do we do so much of our analysis of AC circuits in terms of what they do when you put a sine wave through them?

All AC waveforms can be considered as being the sum of sine waves of various frequencies. The mathematical technique behind this is known as Fourier analysis. We are not going to get into the mathematics here, but we will consider the implications.

What the maths says is that we can treat any continuous periodic waveform (such as all the ones in Figure 4.3) as the sum of a number of sine waves of various frequencies. The frequencies will all be whole number multiples of the frequency of the repeating periodic waveform. So a 1 kHz triangle wave can be considered to be the sum of sine waves of 1 kHz, 2 kHz, 3 kHz . . . and so on. The amplitudes and phases of the sine waves will vary, generally getting less with frequency, but we could, if we knew them, and had the means to do it, reconstitute the waveform, like baking a cake to a recipe. For instance, the 'recipe' for a square wave of 1kHz is:

1 kHz sine wave, at 1 V RMS, plus ...
3 kHz sine wave, at $\frac{1}{3}$ V RMS, plus ...
5 kHz sine wave, at $\frac{1}{5}$ V RMS, plus ...
7 kHz sine wave, at $\frac{1}{7}$ V RMS, plus ...
. . .
n kHz sine wave, at $\frac{1}{n}V_{RMS}$.

'*n*' can be any whole number as high as you care to keep going. The higher in frequency you continue, the better the shape of the resulting wave – that is the closer to the ideal, with the voltage changing from one voltage to the other almost instantaneously. Real square waves are not ideal, having a finite 'risetime' – the time taken to get from 10 to 90% of the value of the step.

You will notice in our square wave 'recipe' (known more properly as a Fourier series) that we only have the odd number multiples of 1 kHz. The 1 kHz waveform is known as the 'fundamental' of the series (i.e. the sine wave at the same frequency as the periodic waveform being analysed). The sine waves at 2 kHz, 3 kHz, and so on, are known as the 'harmonics' of the fundamental. 2 kHz would be the 2nd harmonic, 3 kHz the third, and so on. So we can say that 'a square wave consists only of the fundamental plus odd harmonics'. It contains no even harmonics. The exact amplitude of the result can be foretold, but we are not often worried about it.

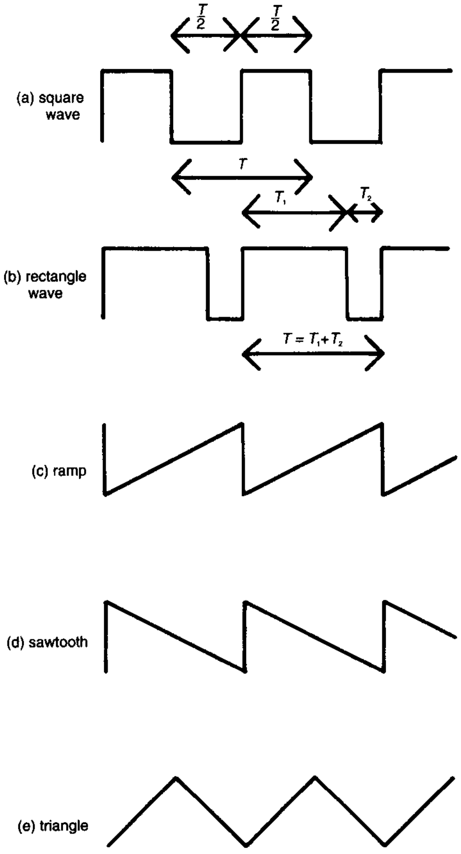

Figure 4.3 More AC waveforms

You can get tables showing the equations to write various waveforms in terms of their harmonics, but we rarely need them. Quite a lot can be done intuitively. Where a waveform has a sharp transition between two levels, that's where you get the high harmonics. The 'frequency response' of a circuit is the way that its output, relative to the input, varies with frequency. If a circuit, such as a low-pass filter (of which more in Part Two) tends to attenuate high frequencies then it will affect the edges of a square wave – they will be slower. If we know the frequency at which the filter begins to 'cut', then we can get an idea of how serious this is – for example if our square wave is at 1 kHz, and the filter starts to 'roll off' from 2 kHz, the effect will be quite noticeable. If the filter rolls off from 20 kHz, much less so. Conversely, the low frequencies of a waveform contribute most to the portions where it changes slowly, or not at all; the top and bottom of a square wave will tend to 'sag'. The time responses of 1st order circuits, which we look at in Chapter 9 are in fact extreme examples of this.

More AC waveforms

Figure 4.3 shows some types of AC signal which are commonly encountered. There is not too much to know about them, except to recognize their shapes and their names. With rectangle waves we sometimes hear talk of mark-to-space ratio. This is the ratio of duration of the more positive part to the more negative – $T_1 : T_2$ on the diagram. These waveforms are best specified, amplitude-wise, in terms of pk–pk level, again the difference between the positive and the negative voltage. Time-wise, we obviously refer to them by either their frequency or their period, with $f = 1/T$ once again.

AC waveforms with a DC level

It often happens that we come across signals which are a combination of AC and DC. Then we say that the waveform has a 'DC level'. The DC level of an AC waveform is just its average level. Hence if it has an equal area below 0 V as above it has a DC level of zero.

Sine waves, square waves, ramps, sawtooths and triangles have a DC level of zero if they move between equal positive and negative voltages. Rectangle waves with uneven mark-to-space ratios (if they didn't have they'd be square waves) will go more positive than negative (ratio less than 1:1) or more negative than positive (more than 1:1) to have no DC level. In fact changing their mark-to-space ratio changes their DC level too, assuming that they stay between the same two voltages.

Figure 4.4 shows some examples. The triangle wave goes between 1 and 9 V and so it has a DC level of 5 V. This is the case regardless of the duration of its ramps. (Sketch one of any shape on squared paper and then draw a line horizontally through its mid point. You should see that its area above the line is the same as that below. This is true for sines, squares, sawtooths and ramps as well.) So the DC level of any sine, square, ramp, sawtooth or triangle is:

$$V_{DC} = \frac{V_+ + V_-}{2} \tag{4.9}$$

For the triangle in Figure 4.4, $V_{DC} = (9 + 1)/2 = 5\text{V}$.

The rectangle wave goes between +5 V and −5 V. But it has a mark-to-space ratio of 3:1, and so has a positive DC level, as the area above 0 V is greater than that below. The DC level is given by:

$$V_{DC} = \frac{T_M}{T} V_M + \frac{T_S}{T} V_S \tag{4.10}$$

T_M is the duration of the mark, V_M its voltage, T_S and V_S the same for the space. T is the period, $T_M + T_S$. So for our example:

$$V_{DC} = 0.75 \times 5 - 0.25 \times 5 = 2.5\,\text{V}$$

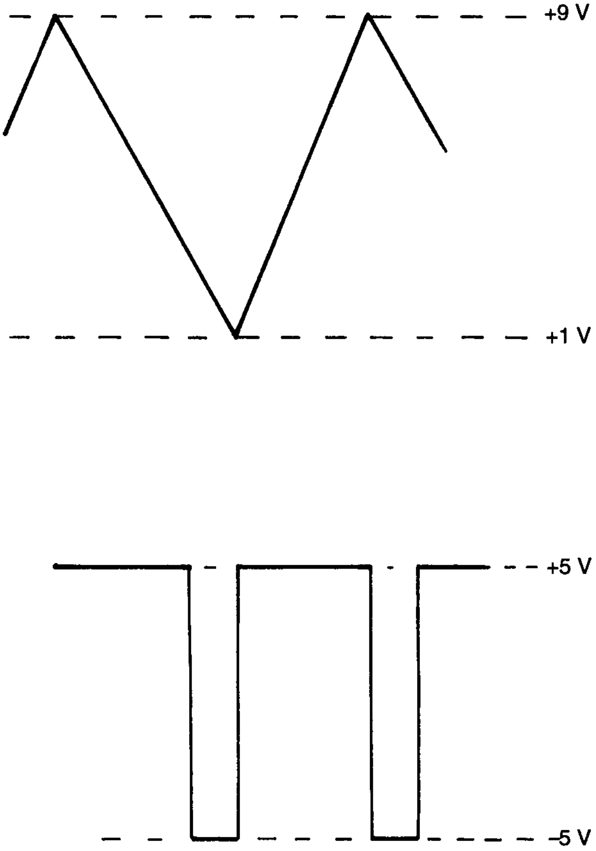

Figure 4.4 AC waveforms with DC level

Power calculations with AC waveforms

For power calculations involving AC waveforms, we must use the RMS value of the signal. RMS stands for 'root-mean-square'. It is what we get when we take the average of the square of the amplitude of a waveform over its cycle, and then take the square root of that. If that sounds like a rigmarole, it is, but we never actually have to do it.

Sine waves

We already know how to find the RMS value of a sine wave from our discussions on amplitude earlier in this chapter. When calculating the power that a sinusoidal signal develops in a load we must also take account of the phase angle between voltage across and current through that load.

The power dissipated by a circuit element which is passing a sinusoidal current (with no DC) is defined as:

$$P = VI \cos\phi \tag{4.11}$$

where P is the power in watts, V is the RMS voltage across the component in volts, I is the RMS current in amps and ϕ is the phase angle between voltage and current.

The $\cos\phi$ term varies between 1 when $\phi = 0°$ and 0 when $\phi = 90°$ (or $-90°$). Hence for resistors, for which $\phi = 0°$ always, we simply use the same power equations that were given for DC circuits in Chapter 3, of course using RMS values. Equally we can say that ideal capacitors and inductors, for which $\phi = 90°$ (or $-90°$), don't dissipate power. When we use circuits made up of combinations of these components, and ϕ is between 0 and 90°, the power will be somewhere between zero and 'volts-times-amps'. But all of that power will be dissipated in the resistive components of the circuit.

(An aside: the term 'peak power' is sometimes heard, but has no relationship to 'pk amplitude'. It is used in such things as sound amplification systems to describe the the maximum amount of electrical power delivered to a loudspeaker at any given moment. There is no such thing as pk–pk power. Thought I'd mention it.)

RMS values of other waveforms

Its not often that we have to calculate these, but if we do it's nice to know how. If you're a beginner you may well prefer to skip this. I just couldn't resist putting them in.

For any triangle, ramp or sawtooth wave with no DC level, and a positive excursion, V_{PK}:

$$RMS_{\text{triangle}} = \frac{V_{PK}}{\sqrt{3}} = 0.577\ V_{PK} \tag{4.12}$$

For any rectangle wave (of which a square wave is just a special case), if T_M is the duration of the mark, V_M its voltage, T_S the duration of the space, V_S its voltage and T the period $(T_M + T_S)$:

$$RMS_{\text{rectangle}} = \sqrt{\left(V_M^2 \frac{T_M}{T} + V_S^2 \frac{T_S}{T}\right)} \tag{4.13}$$

with V_M the voltage of the mark and V_S that of the space. This takes into account the DC level.

For a signal with AC and DC components:

$$RMS_{\text{AC+DC}} = \sqrt{\left(V_{\text{DC}}^2 + V_{\text{RMSAC}}^2\right)} \tag{4.14}$$

And finally, for a 'piecewise' signal with known RMS values over different parts of its period

$$RMS_{\text{total}} = \sqrt{\left(V1_{\text{RMS}}^2 \frac{t1}{T} + V2_{\text{RMS}}^2 \frac{t2}{T} + \ldots + Vn_{\text{RMS}}^2 \frac{tn}{T}\right)} \tag{4.15}$$

We can see that Eqn (4.13) is just a special case of this.

By way of illustration:

Example 4.1: The triangle wave of Figure 4.4 has an AC component that goes between +4 V and −4 V. Its RMS value is therefore 0.577 × 4 = 2.31 V. It has a DC component of 5 V, so the true RMS value is:

$$RMS_{\text{triangle}} = \sqrt{(5^2 + 2.31^2)} = 5.5\,\text{V}$$

Example 4.2: A signal consists of a high frequency sine wave of 5 V pk for 400 ms with no DC, followed by a DC voltage of 2 V for 300 ms. What is the RMS value?

RMS value of the sine wave is 5 × 0.707 = 3.54 V

$$RMS_{\text{total}} = \sqrt{\left(\frac{4}{7} \times 3.54^2 + \frac{3}{7} \times 2^2\right)} = 2.98\,\text{V}$$

5 A circuit analysis toolkit

Introduction

This chapter is intended as a quick guide to the basic techniques of network analysis. The mathematical requirements are minimal; you need to be able to transpose equations and solve simultaneous equations by substitution. We also get to consider some characteristics of real voltage and current sources, which ties in nicely with some of the analysis tools presented.

We will take DC circuits for all of our examples, as this is the easiest way of demonstrating the techniques. Everything said applies equally to AC circuits as well, but you generally need to use complex numbers (see Chapter 4 and Appendix 4) to take account of phase if there are capacitors and inductors present, or sources at different phases.

Basic topologies

There are two basic shapes that electric and electronic circuits come in; series and parallel. Each has associated with it one of two electrical laws which tell us how to go about calculating the voltages and currents in that circuit.

The series circuit and Kirchhoff's voltage law

A series circuit is represented in Figure 5.1. The components are an input voltage, V, 10 V DC, and three resistors: R_1, 1k; R_2, 2k2; and R_3, 4k7. We have also labelled on the drawing, for our convenience, the voltages across each resistor, V_1, V_2 and V_3. The voltages are labelled with arrows. With DC voltages we follow a convention of putting the head of the arrow to the more positive end of the component.

The key to analysing a series circuit is to remember that the current is identical through each component in the loop. (We can also say that connecting the components in a different order will not affect that current.) Hence the current in the loop is labelled just once, this time with an arrow on the loop, with the legend I next to it to identify it. The head of the arrow shows the direction of current flow.

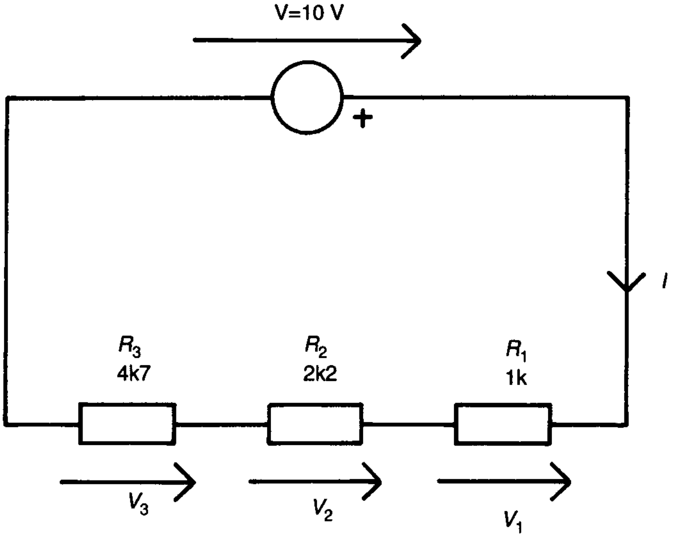

Figure 5.1 Series circuit

Example 5.1: Suppose that we wish to calculate V_1, V_2 and V_3. How do we do it? We need to find the value of current, I. Then we will be able to calculate each voltage using Ohm's Law.

We can find the total resistance as described in Chapter 2. In our case:

$$R_S = 1\text{k} + 2\text{k}2 + 4\text{k}7 = 7900\,\Omega$$

Now we can say that:

$$I = \frac{10}{7900} = 1.27\,\text{mA}$$

Now we can use Ohm's Law to find V_1, V_2 and V_3:

$$V_1 = 1.27\,\text{mA} \times 1\text{k} = 1.27\,\text{V}$$
$$V_2 = 1.27\,\text{mA} \times 2\text{k}2 = 2.78\,\text{V}$$
$$V_3 = 1.27\,\text{mA} \times 4\text{k}7 = 5.95\,\text{V}$$

Kirchhoff's voltage law states that, in any loop of voltages on a circuit, their sum will be zero if we take the clockwise ones as being positive, the anticlockwise ones as negative (or vice versa). Put another way, the clockwise ones equal the anticlockwise ones. This enables us to check our calculations: 1.27 + 2.78 + 5.95 = 10V – we did it right. In any mathematical analysis of a circuit, its always good to have a way to check our result, and using voltage loops is one way.

The parallel circuit and Kirchhoff's current law

Example 5.2: Figure 5.2 shows a basic parallel circuit made with the same components. With parallel circuits the rule is that the voltage across all the branches is identical. Hence there is only one voltage to be labelled, the source voltage. But there are four currents: I, the current leaving the voltage source, and I_1, I_2 and I_3, the currents through the resistors. We would like to calculate them.

We can see that the voltage across each resistor is the same; the 10 V source voltage. Therefore we can apply Ohm's Law directly to each branch of the circuit to find I_1, I_2 and I_3:

$$I_1 = \frac{10}{1k} = 10 \text{ mA}$$
$$I_2 = \frac{10}{2\text{k}2} = 4.55 \text{ mA}$$
$$I_3 = \frac{10}{4\text{k}7} = 2.13 \text{ mA}$$

Kirchhoff's current law states that the total of currents entering and leaving any 'node' (a node is any place where two or more conductors join) is zero. This enables us to calculate the current I:

$$I = I_1 + I_2 + I_3 = (10 + 4.55 + 2.13)\text{mA} = 16.68\,\text{mA}$$

We know that the resistance between any two points is the ratio of the voltage across them and the current passing between them. So in this case the resistance is:

$$R_\text{P} = \frac{10}{16.68\,\text{mA}} = 600\,\Omega$$

We could have calculated the parallel resistance directly, by using the formula from Chapter 2:

$$\frac{1}{R_\text{P}} = \frac{1}{1\text{k}} + \frac{1}{2\text{k}2} + \frac{1}{4\text{k}7} = 1.67\,\text{m}\,\Omega$$

So:

$$R_\text{P} = \frac{1}{1.67\,\text{mA}} = 600\,\Omega$$

Again we have cross-checked our result, and it's fine.

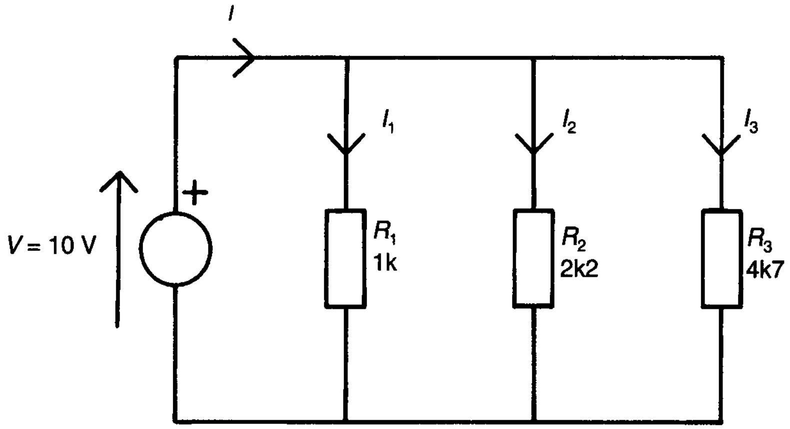

Figure 5.2 Parallel circuit

Arrow directions for voltages and currents

It is worth taking a moment to think about the rules that we apply when adding voltages and currents in using Kirchhoff's two theorems, as it can be surprisingly easy to confuse ourselves.

Here's the rules. If we follow these, things work:

1. The arrows for voltage across and current through a voltage or current source must point in the same direction.
2. The arrows for voltage across and current through a resistance must point in opposite directions.
3. For a voltage loop, the sum of arrows going clockwise equals the sum of arrows going anti-clockwise.
4. For a node, the sum of currents entering a node equals the sum of currents leaving the node, as denoted by the arrows' directions.

In the above examples, it was obvious which end of the resistors would be more positive and in which direction currents would be flowing. Hence drawing the arrows was easy.

In other instances it will not be obvious, when labelling currents and voltages at the start of the analysis, which end of the component is the more positive. Such a situation is shown in Figure 5.3. We wish to know the voltage V_2, but this voltage is affected by both voltage and current sources which have a tendency to create voltages of opposite polarity across R_2. The way to approach this sort of problem is not to worry about the polarity of the voltage; if we label it in the wrong direction, the voltage will come out as negative in solving the equations. We simply get on with labelling the voltages and currents (following rules 1 and 2), then we can write equations for voltage loops (using rule 3, the voltage law) or nodes (with rule 4, the current law).

Example 5.3: Solve Figure 5.3.

For node A, we can write:

$$I_1 = I_2 + 10\,\mathrm{mA}$$
$$I_2 = I_1 - 10\,\mathrm{mA} \quad \text{(call this Eqn (A))}$$

For the loop on the left we can write:

$$V_{IN} = V_1 + V_2$$
$$V_2 = V_{IN} - V_1$$

(but $V_1 = I_1.R_1 = 10\,\mathrm{k}.I_1$ and $V_2 = I_2.R_2 = 2\,\mathrm{k}2.I_2$)
so:

$$2\,\mathrm{k}2.I_2 = 5 - 10\,\mathrm{k}.I_1$$
$$I_2 = \left(\frac{5 - 10\,\mathrm{k}.I_1}{2\mathrm{k}2}\right)$$
$$I_2 = 2.27\,\mathrm{mA} - 4.55.I_1$$

We can substitute this back into Eqn (A), giving:

$$2.27\,\mathrm{mA} - 4.55.I_1 = I_1 - 10\,\mathrm{mA}$$
$$I_1(1 + 4.55) = 2.27\,\mathrm{mA} + 10\,\mathrm{mA}$$
$$I_1 = \frac{12.27\,\mathrm{mA}}{5.55} = 2.21\,\mathrm{mA}$$

So, again from Equation A:

$$I_2 = 2.21\,\mathrm{mA} - 10\,\mathrm{mA} = -7.79\,\mathrm{mA}$$

and therefore

$$V_2 = I_2.R_2 = -17.1\,\mathrm{V}$$

and

$$V_1 = 2.21\,\mathrm{mA} \times 10\mathrm{k} = 22.1\,\mathrm{V}$$

Our solution is: $V_1 = 22.1$ V, $I_1 = 2.21$ mA, $V_2 = -17.1$ V, $I_2 = -7.79$ mA. We can now redraw the circuit, reversing the direction of the arrows where our solution gave a minus sign (Figure 5.4). A few seconds of calculator-punching demonstrates that nothing went wrong with the number crunching, and the solution obeys the voltage and current laws. There are quicker ways to get to this result, but as a 'swiss army knife' technique, this is a good one to have. Soon we get some better ones still.

More about voltage and current sources

The voltage and current sources that we considered above were 'ideal' – that is, we consider that they will supply their correct voltage or current, regardless of what load is placed on them. (As such, they have no real existence.) For the ideal voltage source, we could say that the change in voltage across it is zero for any change in output current. This means that a notional quantity which we call its 'internal resistance' is also zero, by Ohm's Law. For the current source we could say that the change in output current is zero for any change in output voltage. Hence its internal resistance is infinite. Real voltage and current sources are not ideal, and we have a way to represent this in our circuits (see Figure 5.5).

We give our ideal voltage source a series resistor, R_S. The closer this resistor is to a short circuit the closer the source is to ideal. If we connect a real voltage source to too low a load resistance the voltage across the load will drop (and the source could be damaged).

The current source is given a parallel resistor, R_P; the closer this is to an open circuit, the better the source. If we connect a real current source to too high a load resistance the current through the load will drop.

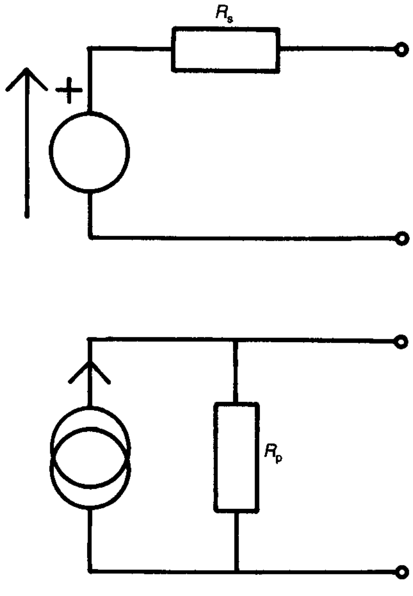

Figure 5.5 Representation of non-ideal sources

These circuit representations of real voltage and current sources are invaluable for circuit analysis, as we will now see. It is possible for any network of voltage sources, current sources and resistances to be replaced by either a single ideal voltage source with a series resistor, or a single ideal current source with a parallel resistor.

Thévenin's and Norton's equivalent circuits

The techniques that we used in the last example of circuit analysis are fine for instances where we can get a solution for the circuit by writing two or three simultaneous equations and solving them. If the network gets much more complicated than that, however, the amount of maths involved can get pretty tedious, and it can get time consuming to arrive at the correct result without making a numerical error. Also, we have only solved the network for one value of load resistance; if we want to see what happens with a different value, we must do the calculations again. This is where replacing whole lumps of circuit with an equivalent non-ideal current or voltage source is great.

Here's how we go about finding the right values for our equivalent circuit:

Replace with a voltage source (Thévenin's equivalent circuit):

1. Cut the network at two places to isolate the section to be replaced.
2. Calculate the voltage at the load terminals with no load connected (called the 'open circuit voltage' or V_{TH}).
3. Calculate the equivalent resistance looking into the load terminals when any voltage sources are replaced with a short circuit and any current sources with an open circuit (called the 'output resistance' or R_{TH}).

Example 5.4: What is the voltage across R_L in Figure 5.6?

First we separate out the 12 V and the 3 mA source, and combine then into a single voltage source (– Figure 5.7). The points where we cut are labelled A and B. Replacing the 12 V source with a short and the 3 mA one with an open, we get $R_{TH} = 1\text{k} + 1\text{k} = 2\text{k}$ (Figure 5.8). When we calculate the open circuit voltage, we get 3 mA × 1k = 3 V across R_2, and nothing across R_3, which has no current flowing in it. Hence V_{TH} is 12 – 3 = 9 V.

The equivalent circuit is replaced into the original in Figure 5.9. Things are getting easier! Now we can cut and replace at the load terminals themselves, L_1 and L_2. This time we'll replace with a current source.

Looking into L_1 and L_2 with both sources replaced by a short, we get 2k in parallel with 2k, so R_N is 1k. (Figure 5.10).

To calculate short circuit current, we replace R_L with a short, and then calculate the current through the two resistors; 2.5 mA and 4.5 mA as shown on the drawing, taking care to label directions correctly. I_N is then clearly the difference between the two (by Kirchhoff's current law), 2 mA. So Figure 5.11 shows the equivalent circuit with R_l now connected. If R_l is 1 kΩ, parallel resistance with R_N is 500 Ω, and voltage across R_l is 1 V, terminal L_1 being most positive.

Naturally we want to check, and the easiest way to do this is to redraw the original circuit, labelling in voltages and currents, using Ohm's Law and voltage and current laws, and working backwards from R_1. If there is a problem it will become apparent. We find we are OK (see Figure 5.12).

We now could find the current through any other load using our existing solution – no need to do all that number-crunching again.

The network can now be replaced with an ideal voltage source equivalent to V_{TH}, in series with a resistor equivalent to R_{TH}.

Replace with a current source (Norton's equivalent circuit):

1. Cut the network at two places to isolate the section to be replaced.
2. Calculate the current at the load terminals when they are short circuited (called the 'short circuit current' or I_N).
3. Calculate the equivalent resistance looking into the load terminals when any voltage sources are replaced with a short circuit and any current sources with an open circuit (called the 'output resistance' or R_N).

The network can now be replaced with an ideal current equivalent to I_N, in parallel with a resistor equivalent to R_N.

6 Equivalent resistances

Introduction

Resistors can be bought in certain standard values. The ranges of values are commonly called the E6, the E12 and the E24 series, the numbers denoting the quantity of values per decade of resistance. For building or repairing low voltage electronic circuits most workshops will stock a full range of E12 or E24 miniature resistors (i.e. 1/8 W or 1/4 W power rating), usually 1 or 2% tolerance, plus a selection of resistors rated at higher powers, which are available in combinations of E6 and E12 values. An additional range, E96, is also available, but these are more expensive, 0.1% tolerance, and few workshops will stock them as standard due to the large number of values. Also they are hard to obtain below 100 Ω or over about 250k.

The standard values are almost always fine, but once in a while you need a value that lies between two of them. This can be achieved by combining two components in series or parallel, their values being chosen so that the overall equivalent is near enough.

It is evident that choosing the best pair of resistors for this purpose might involve a fair amount of trial and error with a calculator, and that several near solutions might exist. For this purpose, three 'Tables of equivalent resistance' are provided in the rest of this chapter. Table 6.1 is for E6, Table 6.2 for E12, and Table 6.3 for E24. You should use the appropriate one for the range of components which you intend to use.

Using the Tables for resistors

Each table shows all achievable values between 1k and 10k with two resistors. s denotes series connection and p denotes parallel. The tables are sorted in order of ascending equivalent resistance.

Example 6.1: Choose a pair of E24 resistors to give an equivalent resistance of 7k7.

From Table 6.1:

R_E	R_1	s/p	R_2	P_{REL}
7700	200R	s	7k5	1.03
7700	1k5	s	6k2	1.24
7700	3k	s	4k7	1.64

There are plenty of others that would be close enough too.
To get a value of less than 1k, or greater than 10k, you should scale all values by factors of ten as necessary.

Example 6.2: Choose a pair of E24 resistors to form a resistance of 125k.

R_E	R_1	s/p	R_2	P_{REL}
1250	1k5	p	7k5	1.2

125k is 1250 multiplied by 100, so resistors of 150k (1k5 times 100) and 750k (7k5 times 100), connected in parallel, form a resistance of 125k.

Maximum power rating of the pair

Each line of the table gives a value of P_{REL}. Where each resistor of the pair is of the same power rating, this can be used to find the overall power rating of the pair. It is always a number between 1 and 2. For example, if a pair of 1/4 W resistors are used and P_{REL} has a value of 1.2 then the power rating of the pair is equal to:

$$0.25 \times 1.2 = 0.3\,\text{W}$$

In this way, the pair of resistors can be lumped and considered as a single circuit element.

Tolerance of components

If two components of the same tolerance are used the tolerance of the equivalent resistance is the same.

Using the Tables for capacitors and inductors

Both inductors and capacitors are normally bought in combinations of the standard E6 and E12 ranges. Like resistors, they can be combined in series or parallel to obtain non-standard values. As was discussed in Chapter 2, inductors in series and parallel obey the same rules as resistors, while capacitors in series behave like resistors in parallel, and vice-versa.

Hence, the tables can be used to find equivalent capacitance or inductance. For capacitors, you should read p for s and s for p.

Example 6.3: To form a capacitor of 3n1 using a range of 1 %, E12 capacitors:

R_E	R_1	s/p	R_2	P_{REL}
3090	390R	s	2k7	1.14
3095	3k9	p	15k	1.26
3116	3k3	p	56k	1.06

This gives three alternatives: 2n7 p 390p, 3n9 s 15n and 3n3 s 56n. All three form a capacitor of 3n1, 1 %. However, as capacitors (and inductors) tend to increase in physical size with increasing value the first might be preferable.

7 Maximum powers for resistors

Tables 7.1–7.6 show the voltage across or current through standard value resistors which are equivalent to a selection of common rated maximum powers.

As discussed in Chapter 3, it is wise to avoid running components continuously at full rated power. A good rule of thumb is not to exceed half of rated power; that is roughly 0.7 times the value of voltage or current presented here.

8 Voltage dividers

Introduction

Figure 8.1 shows a voltage divider. It is used everywhere in electronics to reduce the level of AC and/or DC voltages. The attenuation, input resistance and output resistance are as follows:

$$A = \frac{R_2}{R_1 + R_2} \tag{8.1}$$

$$\mathrm{dB} = -20\,\log_{10}(A) \tag{8.2}$$

$$R_I = R_1 + R_2 \tag{8.3}$$

$$R_O = \frac{R_1 R_2}{R_1 + R_2} \tag{8.4}$$

All of these parameters are given in Table 8.1 for various combinations of E24 resistor, and sorted in order of increasing attenuation. The Table starts at 1 dB and ends at 60 dB.

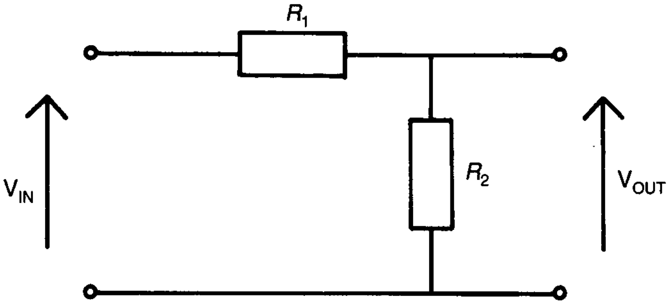

Figure 8.1 A voltage divider

The equations assume that the circuit is driven by a perfect voltage source, i.e. a circuit with zero output impedance, and drives a circuit of infinite input impedance. If the source is the output pin of an op-amp, and the load a non-inverting op-amp circuit, this is as true as makes no difference. If source resistance is a tenth of R_I, or load impedance ten times R_O, then the error is just under a dB; if the ratios are 100:1, then it is less than 0.1 dB.

Using Table 8.1 in cases where source and load impedances can be ignored

We can simply look up the desired attenuation in column A or dB as appropriate, and choose a pair.

Example 8.1: A voltage divider of 4 dB could be formed by resistors $R_1, R_2 = 3k6, 6k2$ and 3k, 5k1 respectively, amongst many.

When source and load impedances cannot be ignored

Selecting values for a voltage divider with ideal source and load impedances is pretty straightforward, as we saw above, but what happens when source and load begin affecting the nominal attenuation noticeably? Let us consider what happens.

We'll call source impedance R_S, input and output impedances of the attenuator R_I and R_O, as before, and load impedance R_L. Ideally, we want R_I to be much greater than R_S, and R_L much greater than R_O. This implies that (as R_O cannot be greater than R_I) R_L should be much greater than R_S.

(Of course, the situation can arise where the loss due to R_S and R_L is actually greater than the desired attenuation. If we are in doubt, we can check this by calculating a value for $\frac{R_L}{(R_S+R_L)}$; if this gives a greater attenuation than that desired, we need a buffer amplifier, rather than an attenuator.)

In Table 8.1, the columns R_{SMAX} and R_{LMIN} give suggested values for, as their names suggest, a maximum value of R_S and a minimum of R_L. This is calculated so that, with both in place, they cause the circuit to have an attenuation of 1 dB more than the value given in the dB column. This is true so long as R_S is still less than or equal to R_{SMAX}, and R_L greater than or equal to R_{LMIN}. The column R_{LS}(1 dB) is the ratio of them.

(If we wish, we can scale both R_1 and R_2 by factors of 10 in the same sense. Then R_I, R_O, R_{SMAX} and R_{LMIN} will also be scaled. A, dB and R_{LS}(1 dB) will be unaffected.)

If we set out to design an attenuator to work in a circuit where R_S and R_L are significant, we can start out by calculating their ratio, $\frac{R_L}{R_S}$. I'm going to call this R_{LS} (real). Two possible situations now arise:

1. If R_{LS} (real) is greater than or equal to R_{LS}(1 dB) for the desired value of dB in

Table 8.1, the attenuation with R_L and R_S in place should be within 1 dB of nominal. (Provided that we can find a pair where $R_S \le R_{SMAX}$ and $R_L \ge R_{LMIN}$.)

2. If R_{LS} (real) is less than R_{LS}(1 dB) the error will be more than 1 dB. In this situation the problem could be approached by other methods, or the values in the table used as a starting point.

Having selected a pair of values, we can check them numerically, if we are concerned about the accuracy. First we calculate the parallel resistance of R_L and R_2:

$$R_P = \frac{R_L R_2}{R_L + R_2} \tag{8.5}$$

Then:

$$\text{attenuation} = \frac{R_P}{R_S + R_1 + R_P} \tag{8.6}$$

The best way to see how things work is to look at some examples.

Example 8.2: Form a 10 dB attenuator to go between a source of 100 Ω and a load of 10k.

Our ratio of load to source is 100. We look down the dB column at values around 10 dB. R_{LS}(1 dB) is given as 63 or so here, so our error is less than 1 dB. Now look through the available pairs, to find one where we will be able to make R_S and R_L in range. We can see that we will need to divide by 10 to make $R_{SMAX} \ge 100\,\Omega$ and $R_{LMIN} \le$ 10k. We might choose:

R_1	R_2	A	dB	R_I	R_O	R_{SMAX}	R_{LMIN}	R_{LS} (1 dB)
12k	5k6	318m	09.95	17.6k	3.82k	1.03k	65.1k	63.1

This would yield $R_{SMAX} = 103\,\Omega$, $R_{LMIN} =$ 6.51k. We conclude that the error will be around 0.7 dB. (R_S is about equal to R_{SMAX}, so say 0.5 dB, R_L is about 1.5 times R_{LMIN}, we could guess at 0.2 dB. Or we might calculate the actual attenuation using Eqns(3.5) and (3.6). So we aim up the table to lines where dB = 9.3 or thereabouts. We find (again selecting for $R_{SMAX} \ge 100\,\Omega$ and $R_{LMIN} \le$ 10k):

R_1	R_2	A	dB	R_I	R_O	R_{SMAX}	R_{LMIN}	R_{LS} (1 dB)
13k	6k8	343m	09.28	19.8k	4.46k	1.16k	76.1k	65.6

and decide to try $R_1 =$ 1k3, $R_2 = 680\,\Omega$, as $R_{SMAX} = 116\,\Omega$, $R_{LMIN} =$ 7.6k then. To check, we work backwards and calculate that $R_P = 680\,\Omega$ in parallel with 10k, or 634 Ω, and we get:

$$\text{attenuation} = \frac{634}{100 + 1300 + 634} = 0.312 \quad \text{or} \quad 10.1\,\text{dB}$$

which is pretty good.

Here's another example, where the values of R_L and R_S make things tougher.

Example 8.3: An attenuator of 3 dB, with a source of 400 Ω, and a load of 3k.

Here we see that our ratio is a lot lower, $\frac{3000}{400} = 7.5$. If we go to the part of the table where dB = 3, we see that the R_{LS}(1 dB) column gives figures of about 67, telling us that we will lose a lot more than 1 dB due to R_S and R_L. Obviously we need less nominal attenuation; we want the error due to R_S and R_L and the nominal attenuation of the attenuator chosen to total 3 dB.

A possible solution is to use the load resistance itself as R_2. The load is 3k; looking up the table, we see:

R_1	R_2	A	dB	R_I	R_O	R_{SMAX}	R_{LMIN}	R_{LS}(1 dB)
1k2	3k	714m	02.92	4.20k	857	235	15.3k	65.4

which is, by good luck, ideal. R_1 would ideally be 1k2, but we already have a source of 400 Ω, so we want the nearest value to 800 Ω, which is 820 Ω. If we wanted to check, we would calculate $\frac{3000}{3000+400+820} = 0.711 = 2.96$ dB, very close.

Example 8.4: R_S = 1k, R_L = 5k and the attenuation desired is 8 dB.

Here our ratio is again low, 5. Our loss will be too great again, so we look for values of R_2 near to 5k. We find:

R_1	R_2	A	dB	R_I	R_O	R_{SMAX}	R_{LMIN}	R_{LS} (1 dB)
7k5	5k1	405m	07.86	12.6k	3.04k	732	52.3k	71.5

suggesting that we need a series resistor between source and load of (7k5 − 1k), or 6k5. The nearest preferred value is 6k8, giving an attenuation of $\frac{5}{5+6.8+1} = 0.391$ or 8.16 dB, very close.

Note that in cases where the load and source resistances form a part of the attenuator itself, we should check that they have a suitable power rating.

9 First-order CR and LR circuits

Introduction

There are two first-order CR and two first-order LR circuits which we will consider here. One circuit of each type forms an integrator, or a low-pass filter, and one a differentiator, or a high-pass filter. All four circuits can be considered to be variations on the voltage dividers which we looked at in Chapter 8. In each case, either the input resistor or the output resistor is replaced with either a capacitor or an inductor.

Where we call them integrators and differentiators we will look at their output waveforms when their input is a pulse. This is called the time response. Then we will consider their action as filters; that is, we will look at the amplitude and phase of their outputs when the input is a sine wave of varying frequency. This is the frequency response.

The two approaches are in fact different ways of looking at the same thing, which is their transfer function – in other words their output for any given input. Both methods can be both understood and quantified without much mathematics, and one, other or both is usually very helpful when we need to use them in a circuit, or understand their use.

Time response

A quick explanation of CR and LR circuit waveforms

The four circuits, with their associated waveforms, are shown in Figure 9.1.

We assume that the resistance of the source is negligible, and the load on the circuit is high enough to be ignored. Both CR circuits have the same current waveform, and so do both LR circuits. (As discussed in Chapter 5, the current in a series circuit is the same through each of its components, and putting them in a different order makes no difference to that current.) Also, the sum of the capacitor's and the resistor's, or the inductor's and the resistor's, voltages always equals the input voltage (by Kirchhoff's voltage law).

Figure 9.1 First-order circuits – time response

A capacitor will always resist a sudden change in the voltage across its terminals. Hence, when the leading edge of the pulse arrives, its voltage remains, initially, at zero. All of the available voltage is, at that moment, across the resistor. Therefore the current at that moment is $I = \frac{V}{R}$.

The current charges the capacitor, causing its voltage to increase from zero. As this happens the voltage across the resistor decreases. The current (proportional always to the voltage across the resistor) falls accordingly. This in turn slows down the charge rate of the capacitor. Hence the rate of change of the voltage across the capacitor decreases as that voltage approaches the input voltage. The current in the circuit falls from $I = \frac{V}{R}$ towards zero, and the voltage across the resistor falls from V towards zero.

Eventually, the capacitor is fully charged, and the voltage across it is equal to the input voltage. Things will stay like this until the input changes again. When it falls to zero the voltage across the cap cannot change instantly; it must now discharge, back through the resistor, and into the source (the only possible path – remember that the source has a low, and the load a high, resistance). Hence a current of $\frac{-V}{R}$ now flows for an instant (the minus sign indicating that the direction has reversed). This current decreases towards zero again as the voltage which created it, that across the plates of the capacitor, falls. Eventually, there is no charge left in the capacitor, no voltage across its terminals and no current in the circuit. The circuit is once again at rest, as it was in the beginning.

Because an inductor resists a sudden change in current, an LR circuit's current is at zero when the leading edge of the pulse arrives. So then is the voltage across the resistor at that moment. For the sum of the resistor's and the inductor's voltage to equal the input voltage, as it must, the inductor sets up a back EMF across its terminals, opposing the input voltage. The back EMF decays with time, and current begins to flow in the circuit, creating a voltage across the resistor. Eventually there is no back EMF, and the current arrives at a final value of $\frac{V}{R}$. The voltage across the inductor is now zero, and the voltage across the resistor is V.

When the trailing edge of the pulse arrives at the input (i.e. the input voltage falls towards zero again) the current in the circuit also will try to fall to zero. Again the inductor will resist change. To do this it will set up another back EMF, opposing the voltage across the resistor now. This back EMF will also decay with time, allowing the current in the circuit and the voltage across the resistor to fall towards zero.

The only difference between the two CR (or the two LR) circuits is which device, resistor or capacitor (inductor), is on the output side. The voltages across the components, and the currents through them, are identical.

Time constants It can be seen that, essentially, only two waveform shapes exist for both output voltage and for current in all four circuits. These two waveforms are shown in more detail in Figure 9.2.

All of the curves are exponential in shape. How long they take to change from initial to final values is determined by the circuit time constant T (not to be confused with the T used for period of an AC waveform), which is in turn a function of component values in the circuit.

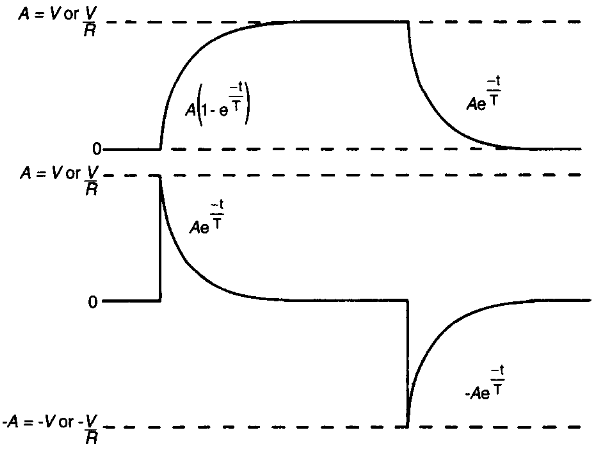

Figure 9.2 Detail of Figure 9.1

The formulae for T are:

for a CR circuit:

$$T = CR \tag{9.1}$$

and for an LR circuit:

$$T = \frac{L}{R} \tag{9.2}$$

T is tabulated for various values of C and R in Table 9.1, and for L and R in Table 9.2. These tables also give values of frequency constants which we will look at later under 'Frequency response'.

The tables are sorted in order of T, increasing for CR and decreasing for LR. T is given in μs. Should we want to obtain a value of T which is outside the range of the table we should do it by scaling one or both components by factors of 10 appropriately. As always, some examples:

Example 9.1: Find values for a CR circuit with T = 56 ns.

From Table 9.1:

f(Hz)	T(μs)	R	C
2842	56.00	1k	56n
2842	56.00	5k6	10n

We want T = 56 ns, so we need to make R and C between them 1000 times smaller. We could for example make $R = 100\ \Omega$ and C = 560p, or $R = 56\ \Omega$ and C = 1n.

Example 9.2: Find values for an LR circuit with $T = 4\,\mu$s.

From Table 9.2:

f(Hz)	$T(\mu$s)	R	L
4063	39.17	1k2	47m

To make T 10 times smaller we could either make R 10 times larger or L 10 times smaller. So R = 12k and L = 47m or R = 1k2 and L = 4.7m would both work.

Values of voltage and current as a function of t and T Once we have determined a value of T, we can find the value of V_t or I_t, that is output voltage for any moment in time, t, after the rising or falling edge of the input waveform. The formulae are as follows.

For a curve going from zero to a final value:

$$V_t \text{ or } I_t = \left(V \text{ or } \frac{V}{R}\right)\left(1 - e^{\frac{-t}{T}}\right) \tag{9.3}$$

and for a curve going back down to zero:

$$V_t \text{ or } I_t = (-)\left(V \text{ or } \frac{V}{R}\right)e^{\frac{-t}{T}} \tag{9.4}$$

Table 9.3 gives values of Eqns (9.3) and (9.4) for various values of $\frac{t}{T}$.

Example 9.3: Find out to what the voltage out from a 2k2, 1μF differentiator will be after 6 ms, when the input is a rising edge of 6 V:

First we calculate T, from Eqn(9.1).

$T = CR = 2\text{k}2 \times 10\text{u} = 22\,\text{ms}$

Now we evaluate $\frac{t}{T}$. If t = 6 ms, $\frac{t}{T} = \frac{6}{22} = 0.27$. Referring to Figures 9.1 and 9.2, we see that the waveform is a rising edge, governed by the $1 - e^{\frac{-t}{T}}$ function. So we use Table 9.1 to find a value for that function where $\frac{t}{T} = 0.27$. We find:

$\frac{t}{T}$	$1 - e^{\frac{-t}{T}}$	$e^{\frac{-t}{T}}$
0.3	0.7408	0.2592

which is the nearest to 0.27. The final value of the voltage will be 6 V. So its value after 6 ms will be 0.741 × 6 = 4.45 V.

Example 9.4: Design a circuit whose output voltage will be −7 V 220 ms after the falling edge of a + 10 V pulse input. Give a CR and an LR alternative.

By referring to Figure 9.1, we see that the circuit must be a differentiator, as that circuit has an output voltage which goes from $-V$ to 0 after the falling edge of the input. The equation for that curve is $-Ve^{\frac{-t}{T}}$, where $V = 10$ V in this case. So we can write:

$-7 = -10\,e^{\frac{-t}{T}}$, or $e^{\frac{-t}{T}} = 0.7$

and we can use Table 9.1 in reverse to find:

$\frac{t}{T}$	$1 - e^{\frac{-t}{T}}$	$e^{\frac{-t}{T}}$
1.2	0.3012	0.6988

Now we know that $t = 220$ ms, and that $\frac{t}{T} = 1.2$, so we know that $T = \frac{220}{1.2} = 183.3$ ms. Now we can use Table 9.3 to find suitable C and R values, and Table 9.4 to find L and R.

From Table 9.3:

f(Hz)	T(μs)	R	C
8682	18.33	4k7	3n9

T is in μs, so we need to scale up by $\frac{183.3\,\text{m}}{18.33\,\mu} = 10\,000$. We could do this by multiplying both C and R by 100. So we get $R = 470$ k, $C = 390$ n.

From Table 9.4:

f(Hz)	T(μs)	R	L
8681	18.33	1k8	33m

Here we need to scale by making R smaller and L larger. We could say theoretical values of $R = 18\ \Omega$ and $L = 3.3$ H. A 3.3 H inductor would be huge (though not unknown!), which illustrates why CR circuits tend to be more common than LR ones.

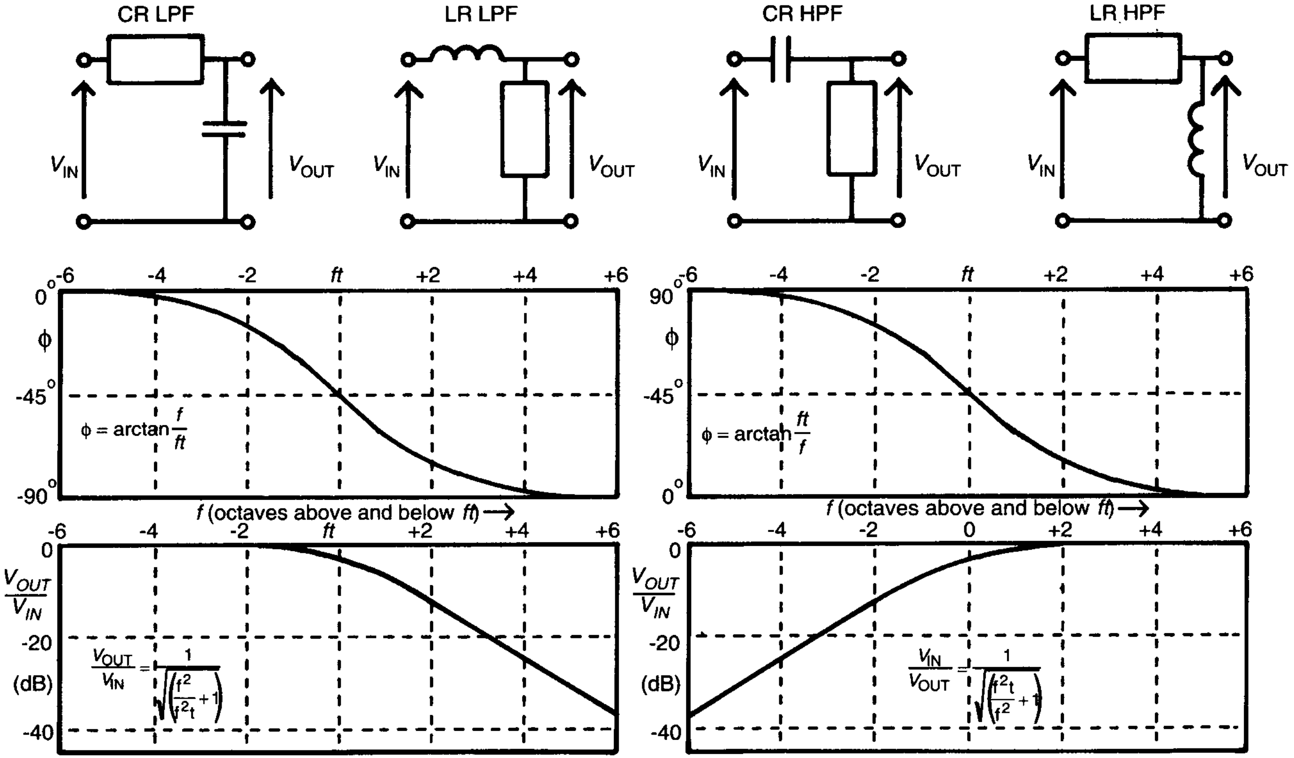

Figure 9.3 First-order circuits – frequency response

Frequency response

Now we look at the behaviour of the same circuits when their input is a continuous sine wave. We are interested in what happens as the frequency of the input is varied.

How first-order filters work

As we saw in Chapter 4, capacitive reactance falls with increasing frequency:

$$X_{\mathrm{C}} = \frac{1}{2\pi fC} \tag{9.5}$$

Inductive reactance increases with frequency:

$$X_{\mathrm{L}} = 2\pi fL \tag{9.6}$$

Each obeys Ohm's Law, in that $V_{\mathrm{C}} = IX_{\mathrm{C}}$, or $X_{\mathrm{L}} = IX_{\mathrm{L}}$ – that is the voltage across a capacitor or an inductor is the current through it multiplied by its reactance, like a resistor. However, whereas voltage and current are in phase with a resistor, they are 90° out of phase with inductors and capacitors.

The four basic filter circuits are shown in Figure 9.3. We can view them all as being similar to the voltage divider which we looked at in Chapter 6, except that one component in each has a 'resistance' which varies with frequency. Hence the overall attenuation of each varies with frequency too.

Where the component on the input side of the circuit has higher impedance at higher frequencies, the circuit is a low-pass filter. These are the two circuits on the left hand side of Figure 9.3, a CR with the capacitor across the output or an LR with the inductor on the input. Conversely, a high-pass filter is formed by a CR with the capacitor on the input side or by an LR with the inductor across the output.

Frequency constants The frequency at which the reactance of the capacitor or inductor is the equal to the resistor is known as the 'turnover frequency' (f_{t}). The attenuation at this frequency is not 6 dB, as it would be if both components were resistive. Because of the fact that the voltage across the reactive component is 90° out of phase with the voltage across the resistor the attenuation is only 3 dB. The turnover frequency can be calculated from the component values (or component values selected to give a desired f_{t}). The governing formulae are:

For a CR circuit:

$$R = \frac{1}{2\pi f_{\mathrm{t}} C}$$

which becomes

$$f_t = \frac{1}{2\pi RC} \tag{9.7}$$

For an LR circuit:

$$R = 2\pi f_t L$$

or

$$f_t = \frac{R}{2\pi L} \tag{9.8}$$

Values for f_t are given in Table 9.1 for CR circuits and in Table 9.2 for LR circuits. As before, component values can be scaled to get frequencies which are outside the range of the table.

Example 9.5: Give component values for a CR filter with $f_t = 12\,\text{kHz}$.

From Table 9.1:

f(Hz)	$T(\mu s)$	R	C
1205	132.00	1k1	120n

We need to multiply the frequency by 10, so we could divide either C or R by 10 to achieve this. So both $R = 110\,\Omega, C = 120\text{n}$ and $R = 1\text{k1}$, $C = 12\text{n}$ would do it.

Example 9.6: Give component values for an LR filter with $f_t = 500\text{kHz}$.

From Table 9.2:

f(Hz)	$T(\mu s)$	R	L
5079	31.33	1k5	47m

We need f_t 100 times larger, so we can make L smaller and/or R larger. We could choose, for instance, $R = 15\text{k}$, $L = 4.7\text{m}$.

Determining the level and phase at any frequency The level of the output voltage, relative to the input, is determined by the ratio of the signal frequency and f_t:

For a LPF:

$$\frac{V_{OUT}}{V_{IN}} = \frac{1}{\sqrt{\left(\frac{f}{f_t}\right)^2 + 1}} \tag{9.9}$$

We can see that when f is much less than f_t, the value of $\frac{V_{OUT}}{V_{IN}}$ is very close to 1, and hence the signal is not much attenuated by the circuit. When $\frac{f}{f_t}$ is much greater than 1, the value of $\frac{V_{OUT}}{V_{IN}}$ approximates to:

$$\frac{V_{OUT}}{V_{IN}} = \frac{1}{\frac{f}{f_t}} = \frac{f_t}{f} \tag{9.10}$$

From this simplified expression, it can be seen that a doubling in frequency will lead to a halving in output signal, or multiplying the input frequency by 10 will reduce its output level to one-tenth. Hence it is customary to say that the filter slope, above the turnover frequency, is −6 db/octave, or −20 dB/decade.

The equation for the attenuation of a HPF is:

$$\frac{V_{OUT}}{V_{IN}} = \frac{1}{\sqrt{\left(\frac{f_t}{f}\right)^2 + 1}} \tag{9.11}$$

and a similar argument applies; this time the slope is −6 dB/octave or −20 dB/decade below the turnover frequency.

These filters affect the relative phase (ϕ), as well as the level, of the signal. The LPF causes the output signal to be between 0 and 90° lagging the input signal, the HPF 0° to 90° leading. In both cases the phase angle is 45° at f_t. These functions are again determined by the ratio of f and f_t:

For a HPF:

$$\phi\,(\text{leading}) = \arctan\left(\frac{f_t}{f}\right) \tag{9.12}$$

For a LPF:

$$\phi\,(\text{lagging}) = \arctan\left(\frac{f}{f_t}\right) \tag{9.13}$$

Hence it is possible to predict both attenuation and phase shift through a filter for any given frequency, provided that f_t is known. Table 9.4 gives both at intervals of a third of an octave, for six octaves either side of f_t.

The first column of Table 9.4 gives the frequency in terms of the number of octaves away from f_t. (The minus sign means higher in frequency for an HPF, lower for an LPF.) The second gives the ratio of frequencies, which we call F (f_t/f for an HPF, f/f_t for an LPF). The third column is the attenuation as the ratio V_{OUT}/V_{IN}, the fourth is attenuation in dBs. The fifth column is the phase shift in degrees.

Example 9.6: What is the approximate attenuation and phase shift at a frequency of 5 kHz for a LPF consisting of a 3n3 capacitor and a 15k resistor?

$$f_t = \frac{1}{2\pi \times 15k \times 3n3} = 3215\,\text{Hz}$$

$$F = \frac{f}{f_t} = \frac{5000}{3215} = 1.56$$

From Table 9.4:

Octaves	F	Att	dB	$\phi°$
0 2/3	01.59	0.533	05.47	57.8

Nearest value in the table is 1.59 (2/3 octave) where attenuation is 5.5 dB, phase shift is 58°.

Example 9.7: A circuit is needed to low-pass filter a signal such that the level at 100 kHz is 15 dB down on the signal below f_t. What would f_t be (using the table to get the nearest approximation)? What will the attenuation be at 50 kHz?

From Table 9.4:

Octaves	F	Att	dB	$\phi°$
2 1/3	05.04	0.195	14.22	78.8

This tells us that for a 14 dB attenuation at 100 kHz, $F = \frac{f}{f_t} = 5$, so $f_t = \frac{100\,\text{kHz}}{5}$, or 20 kHz. At 50 kHz $F = \frac{50}{20}$ or 2.5, and we get:

Octaves	F	Att	dB	$\phi°$
0 2/3	01.59	0.533	05.47	57.8

and the attenuation is 5.5 dB.

10 LC tuned circuits

Introduction

When inductors and capacitors are combined the circuit is called a tuned circuit. Where the circuits in Chapter 9 were termed first-order, we call these second-order, because there are two frequency-dependent elements rather than one. The capacitor and inductor can be combined in either series or parallel, giving rise to two types which we shall consider separately. These circuits both display an effect known as resonance, by which we mean that their impedance is at a minimum or a maximum at one specific frequency.

Series tuned circuit

A series tuned circuit is an inductor and a capacitor in series. A resistive component is also assumed to exist which may be considered to consist solely of the circuit's residual resistances (the inductor's internal resistance being, usually, the only significant one) or perhaps of residual resistances plus a physical resistor. The circuit is shown in Figure 10.1.

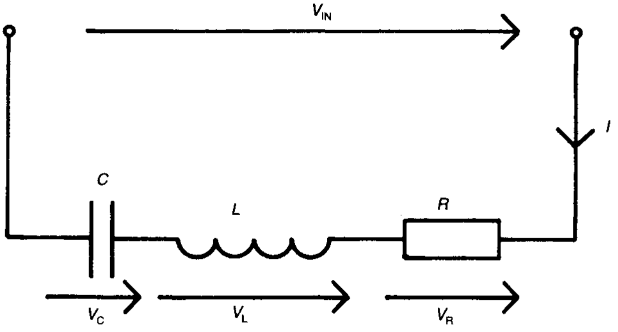

Figure 10.1 Series tuned circuit

What the circuit does

The reactance of the capacitor decreases with frequency, while the reactance of the inductor increases. As we know, we cannot just add the impedance of each component at some frequency together because the phase angles of the voltages will be different. But we can deduce what is happening.

We will take the current in the circuit as being our phase reference, as it is common to all components. The voltage across the capacitor lags it by 90°, the voltage across the inductor leads it by 90° and the voltage across the resistor is in phase with it. The input voltage, which we would divide by input current to find the impedance, will be the phasor sum of these. (If you're a beginner, and this is losing you, look back at 'Calculations on AC quantities' in Chapter 4.)

If X_C decreases with increasing frequency, and X_L increases, then they must be equal at some point. At this frequency the capacitor's and the inductor's voltage are equal, but opposing each other in phase. (Their magnitudes can be calculated by using IX_L and IX_C respectively, and I is the same for each.) This means that they cancel each other – their phasor sum is zero. So the input voltage is equal to the voltage across the resistor – the resistor has the maximum amount of voltage across it that it can have.

This causes the current in the circuit to be at a maximum, and hence impedance is at a minimum, and in phase (resistive). We call this frequency the resonant frequency of the circuit (f_O). Below resonance X_C is greater than X_L, and the impedance is overall capacitive. This means that the current leads the input voltage by some small angle when the impedances are almost equal, and by nearly 90° when the frequency is very low. Above resonance X_L is more significant and the impedance is inductive. Then input voltage leads current by between 0 and 90°.

Calculating resonant frequency

We can deduce the frequency where the two impedances are equal:

$$\frac{1}{2\pi f_O C} = 2\pi f_O L$$

After a little algebra this becomes:

$$f_O = \frac{1}{2\pi\sqrt{LC}} \tag{10.1}$$

The impedance at resonance, which we term Zo is simply:

$$Z_O = R \tag{10.2}$$

Q factor

Although V_C and V_L cancel at resonance, they are still definitely there. In fact they can be larger than the input voltage. This is because the current can be large, given by $\frac{V_{IN}}{R}$, if R is small. The voltage across, say, the capacitor, will be IX_C, or $\frac{V_{IN}}{R} X_C$. We call the ratio of this magnified voltages to the input voltage the Q, or quality factor, of the circuit. Q can be calculated:

$$V_C = \frac{V_{IN}}{R} X_C$$

(because the impedance at resonance is simply R). So:

$$Q = \frac{V_C}{V_{IN}} = \frac{X_C}{R} = \frac{1}{2\pi f_O CR} \tag{10.3}$$

or

$$V_L = IX_L = \frac{V_{IN}}{R} X_L$$

so

$$Q = \frac{V_L}{V_{IN}} = \frac{X_L}{R} = \frac{2\pi f_O L}{R} \tag{10.4}$$

The result should be the same whichever equation we use to calculate Q. From these equations it can be seen that Q can be decreased quite easily by simply adding more resistance in series with the circuit. Conversely the maximum obtainable Q is set by the leftover resistance in the circuit when we have no physical resistor present. The inductor will normally possess far more resistance than the capacitor, so it is common to talk about the Q of an inductor at some specified frequency – this is the highest Q obtainable with that inductor in a tuned circuit with that f_O.

Q as an indication of bandwidth

The fact that the impedance of a series tuned circuit drops to a minimum at resonance makes it very useful for applications where we need some mechanism for picking a certain group of frequencies out of a wideband signal – for instance radio tuners, or audio filters. In these situations we need to know how selective the circuit actually is. The Q factor, conveniently, tells us this – the circuit's bandwidth, or BW. The bandwidth is the difference, in Hz, between the frequencies above and below resonance where the current is 3 dB less than at resonance, for the same level of input voltage – i.e. where the impedance drops by 3 dB. The formula we need is this:

$$BW = \frac{f_O}{Q} \tag{10.5}$$

For circuits of high selectivity (low BW), the requirement is that Q be high, and hence R low. This will influence the selection of components used in the design, particularly that an inductor with low internal resistance be found relative to its impedance at f_O. Often we design the circuit with Q higher than needed, and then add a suitable series resistor, to reduce the bandwidth to the desired value. This is called a 'damping' resistor.

Table 10.1 lists the resonant frequencies from 500 Hz to 50 MHz obtainable with E6 inductors and E12 capacitors. A column is also provided, X, showing the value of X_C or X_L at resonance. This can be used to find the highest possible Q, provided that the resistance of the inductor is known.

Example 10.1: (a) What values of C and L can we use to give a series resonant circuit with $f_O = 8\,\text{kHz}$?

From Table 10.1:

f_O	C	L	X
8k	12n	33m	1.66k
8k	18n	22m	1.11k
8k	120n	3m3	166
8k	180n	2m2	111

This gives us a choice of four pairs.

(b) By consulting suppliers catalogues, we source a 3.3 mH inductor with $R = 6.6\,\Omega$, and a 2.2 mH inductor with resistance, R_L, of 4.1 Ω, What is the best possible Q with each of these? What will the bandwidth be?

With 3.3 mH, X is given as 166 Ω, so Q will be $\frac{166}{6.6} = 25.2$ at best. The bandwidth will be $\frac{8000}{25.2} = 318$ Hz

With 2.2 mH, X is given as 111 Ω, so Q will be $\frac{111}{4.1} = 27.1$ at best. The bandwidth will be $\frac{8000}{27.1} = 295$ Hz

(c) Now calculate values for a series resistor to reduce Q to around 3 for each.

For 3.3 mH: If $X = 166\,\Omega$, and $Q = 3$, then $R = \frac{X}{Q} = \frac{166}{3} = 55.3\,\Omega$. As the inductor already has 6.6 Ω of resistance, we should add a resistor of $55.3 - 6.6 = 48.7\,\Omega$. (with typical inductor tolerances of 10%, 47 Ω would be fine).

For 2.2 mH: $R = \frac{X}{Q} = \frac{111}{3} = 37\,\Omega$. Resistor should be $37 - 4.1 = 32.9\,\Omega$ – say a standard value of 33 Ω.

Parallel tuned circuits

A parallel tuned circuit consists of a capacitor and an inductor in parallel. The circuit can be understood by using a similar approach to the one which we took for the series tuned circuit. However, the practical circuit is slightly complicated by the fact that the inductive branch possesses more resistance than the capacitive branch, which makes it somewhat asymmetrical. In many cases this effect can be ignored, but not all, so we need to be able to predict whether it will be significant or not. But to make the analysis one step at a time, it makes sense to start by considering an ideal version of the circuit, where the effect does not come into play at all.

Example 10.2: If the 2.2 mH inductor of Example 10.1 has a 10% tolerance, how much might f_O and Q vary in practice, assuming that both inductance and resistance increase together?

If the inductance and resistance increase by 10%, we would have $L(\text{max}) = 2.2\,\text{mH} \times 1.1 = 2.42\,\text{mH}$, and $R_{L(\text{max})} = 4.1 \times 1.1 = 4.51\,\Omega$. This would give, using Eqn (6.1):

$$f_O = \frac{1}{2\pi\sqrt{2.42\text{m} \times 180\text{n}}} = 7.63\,\text{kHz}$$

and a corresponding $Q = \frac{2\pi \times 7.63\text{k} \times 2.42\text{m}}{33 + 4.51} = 3.1$
Decreasing by 10% gives $L_{(\text{min})} = 2.2\text{m} \times 0.9 = 1.98\,\text{mH}$ and $\text{R}_\text{L}(\text{min}) = 4.1 \times 0.9 = 3.69\,\Omega$

$$f_O = \frac{1}{2\pi\sqrt{1.98\text{m} \times 180\text{n}}} = 8.43\,\text{kHz}$$

with

$$Q = \frac{2\pi \times 8.43\text{k} \times 1.98\text{m}}{33 + 3.69} = 2.9$$

The ideal parallel tuned circuit

This consists of an ideal inductor and capacitor in parallel – each has no resistance. In this circuit we take the voltage across the circuit, V_{IN}, as our phase reference, as it is common to both components, and look at the current that each branch draws from the source at different frequencies. These currents will always be in antiphase – the capacitor's current, I_C, leading V_{IN} by 90°, the inductor's, I_L, lagging. The input current, I_{IN}, will be their phasor sum. As they are in antiphase, their phasor sum is simply the difference between them.

We can once again say that X_C will fall with increasing frequency, and X_L will rise. And once again, X_C will equal X_L at some frequency, that given by Eqn (10.1). At this frequency, again f_O, the current in each branch will be equal, and hence the input current will be zero. The impedance is $\frac{V_{IN}}{I_{IN}}$, and is infinite. The circuit looks like an open circuit to the source at resonance, and its resonant frequency is calculated identically to that of the series tuned circuit.

Below resonance, the capacitor will have the greater impedance of the two devices, and the impedance will appear inductive with current lagging voltage by 90°. Above, the inductor possesses more impedance and the impedance is capacitive, with V_{IN} in lagging I_{IN}.

At resonance, the input current is zero, while I_C and I_L are $\frac{V_{IN}}{X_C}$ and $\frac{V_{IN}}{X_L}$ respectively. The Q factor, $\frac{I_C}{I_{IN}}$ or $\frac{I_L}{I_{IN}}$ in would therefore be infinite.

The practical parallel tuned circuit

The practical circuit differs from the ideal mostly in that the inductor possesses resistance. Such a circuit is shown in Figure 10.2, with R_L representing the internal resistance of the inductor.

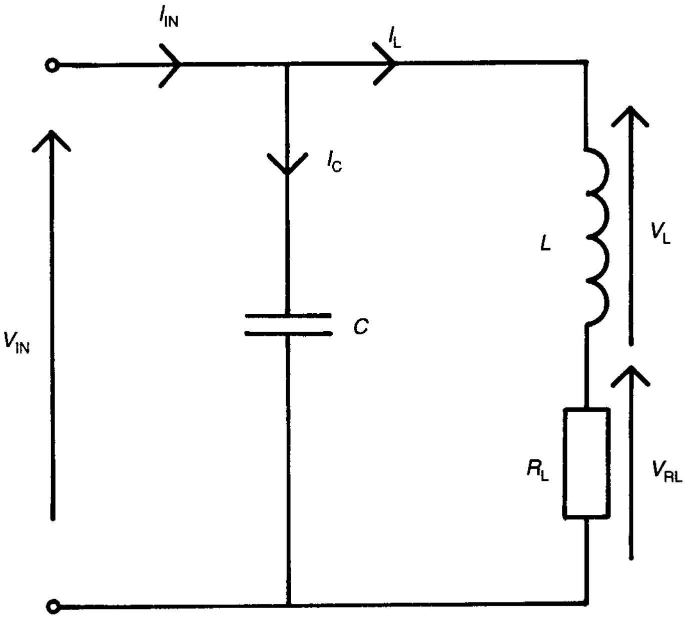

Figure 10.2 Practical parallel tuned circuit

The addition of the resistive element in series with the inductor causes I_L to be less than 90° lagging V_{IN}. In turn, this causes I_{IN}, at the frequency at which $X_C = X_L$, to be leading V_{IN} by some angle, rather than in phase, as it was with the ideal circuit—the circuit is overall capacitive, rather than resistive. To compensate, and bring I_{IN} back in phase with V_{IN}, making the circuit truly resonant, the frequency of V_{IN} must be lowered. This has the effect of making I_C smaller and I_L larger. It can be seen that the effect becomes more pronounced the greater the inductor's resistance is, compared to its reactance.

To what degree all this affects Eqn (10.1) depends on the Q of the inductor at the resonant frequency, as defined in Eqn (10.4).

Resonant frequency error

The resonant frequency as found from Eqn (10.1) must be multiplied by the term:

$$k = \sqrt{1 - \frac{CR^2}{L}} = \sqrt{1 - \frac{1}{Q^2}} \qquad (10.6)$$

to find the true resonant frequency. In practice, the Q has to be pretty low to cause much deviation; a Q of 4 gives $k = 0.97$, a Q of 2 gives $k = 0.87$. Eqn (10.1) is often used as it stands.

Dynamic impedance

The practical circuit no longer looks like an open circuit to the source at resonance. Its impedance is purely resistive however, and is often called the dynamic impedance. It is given by:

$$Z_O = \frac{L}{CR_L} \qquad (10.7)$$

From this we can see that dynamic impedance is inversely proportional to the resistance of the inductor.

Q factor

With the practical parallel tuned circuit the Q is, as with the series resonant circuit, the same as the Q of the inductor at the resonant frequency. We might ask ourselves what happens when we wish to deliberately reduce the circuit's Q; for if we placed our damping resistor in series with the inductor, it would also affect our resonant frequency. The solution is that the damping resistor is placed across the whole tuned circuit, as shown in Figure 10.3, where it has the desired effect without affecting f_O. The value of the damping resistor can be calculated as follows:

$$R_D = Z_O \frac{Q_D}{Q_I - Q_D} \qquad (10.8)$$

where R_D is the damping resistor value, Q_D is the desired Q(*Q damped*), $Z_O = \frac{L}{CR}$ as previously, and Q_I is the Q of the inductor at resonance, or the Q of the circuit with no damping resistor. Q_D must obviously be less than Q_I.

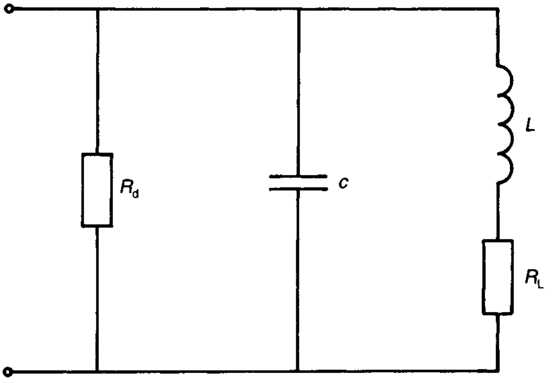

Figure 10.3 Practical parallel tuned circuit with damping resistor

Maximum capacitor value

We can see that as R becomes larger, k Eqn (10.6) goes from 1 towards zero, and the resonant frequency falls, also towards zero. When:

$$\frac{CR_L^2}{L} = 1 \text{ or } C = \frac{L}{R_L^2} \tag{10.9}$$

then $k = 0$, and the circuit ceases to resonate. This tells us that for any practical inductor, there is a maximum value of capacitor which can be placed across it for it to remain resonant. This value is easily calculated from Eqn (10.9).

Example 10.3: design a parallel tuned circuit with $f_O = 120\,\text{kHz} +/-2\,\text{kHz}$, $Q = 20$ and the highest feasible dynamic impedance, with the restriction that C is greater than 100 pF. What is the dynamic impedance, with and without the damping resistor? (Assume that the resistance of the inductor is 5 Ω.)

From Table 10.1, we choose $C = 120\,\text{pF}$, $L = 15\,\text{mH}$, giving a nominal frequency of 119 kHz. We can calculate the Q of the inductor by taking X from the table – 11.2k – and dividing by 5 Ω. This gives $Q = 2240$. Now we calculate Z_O, using Eqn (10.7):

$$Z_O = \frac{15\text{m}}{120\text{p} \times 5} = 25\,\text{M}\Omega$$

and so

$$R_D = 25\text{M} \times \frac{20}{2240 - 20} = 225\,\text{k}\Omega$$

As Z_O is so much larger than R_D, we can take the dynamic impedance with R_D fitted to be equal to R_D, 225 k Ω.

Operational Amplifier Circuits

11 Amplifier gains

Introduction

Operational amplifiers, or op-amps, are perhaps the most common building blocks found in analogue circuits. They can be used to create amplification stages very easily, and many other types of circuit besides. There are very many 'op-amp cookbooks' around that give lots of these circuits, so we won't add to them here. The main purpose of this chapter is to present you with a pair of tables to enable easy selection of resistor values for any desired gain.

We'll take a moment, however, to state the two rules that govern an op-amp's behaviour for the purpose of achieving a first-off analysis of their circuits:

1. The input terminals of op-amps draw no current.
2. The output of the op-amp does whatever it can to keep the voltage between the input terminals at zero.

These two statements are something of a generalization, but they are fine if you want to work out what an op-amp circuit is doing.

There are two common ways to use op-amps as amplifier stages. We look at them next.

Inverting op-amp

Figure 11.1 shows a basic inverting op-amp circuit. This circuit can be used to give either attenuation or gain with two resistors. The output is in antiphase with the input. The gain is given by:

$$A_V = \frac{R_2}{R_1} \tag{11.1}$$

Values of R_1 and R_2 can be found from Table 11.1, where gain is given both as a ratio and in dBs. R_1 and R_2 may, of course, be scaled by factors of 10 without affecting the gain. The Table only shows values above unity gain (0 dB). If you need to select a pair of resistors to give attenuation, then the Table can still be used, but the positions of R_1 and R_2 should be switched. The dB column then reads attenuation directly, or the A_V column the reciprocal of gain expressed as a ratio.

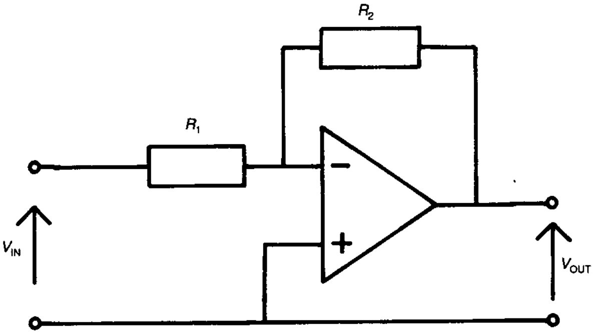

Figure 11.1 Inverting op-amp

The input resistance of the circuit is equal to the value of the input resistor, R_1. The output resistance is, for practical purposes, negligible. (Limitations on its ability to drive a load will be dependent on maximum values of output current, voltage swing and slew rate, for which the manufacturer's data on the chip used should be consulted.)

It is sometimes desirable to limit the frequency response of the circuit. The standard method is to add suitable value capacitors, as in Figure 11.2. C_1, in series with the input resistor, limits low frequency response, while C_2, in parallel with R_2, limits high frequency response. Each gives a 6 dB/octave slope, as for the first order LPF and HPF described in Chapter 9. The equations for the lower −3 dB point, f_{t-}, and the upper −3 dB point, f_{t+}, are also similar:

$$f_{t-} = \frac{1}{2\pi R_1 C_1} \quad \text{and} \quad f_{t+} = \frac{1}{2\pi R_2 C_2} \tag{11.2a}$$

Example 11.1: give suitable values for an inverting op-amp circuit with a gain of 15 dB, and an input resistance of between 20k and 30k. Determine suitable values for C_1 and C_2 to make the upper and lower −3 dB points as near as possible to 100 Hz and 15 kHz respectively, using standard E12 capacitors.

Table 11.1 gives many combinations, close to 15 dB, but to meet the requirement for input resistance R_1 should be between 20k and 30k. We take the pair 2k7/15k, and multiply by 10, so that R_1 = 27k and R_2 = 150k.

To find values for C_1 and C_2, we transpose Eqn (11.2a):

$$C = \frac{1}{2\pi f_t R} \tag{11.2b}$$

and get:

1. C_1 = 59 nF (ideal) – nearest is 56 nF, substitute back into Eqn (11.2) to get f_{t-} = 105 Hz
2. C_2 = 71 pF (ideal) – nearest is 68 pF, giving f_{t+} = 15.6 kHz

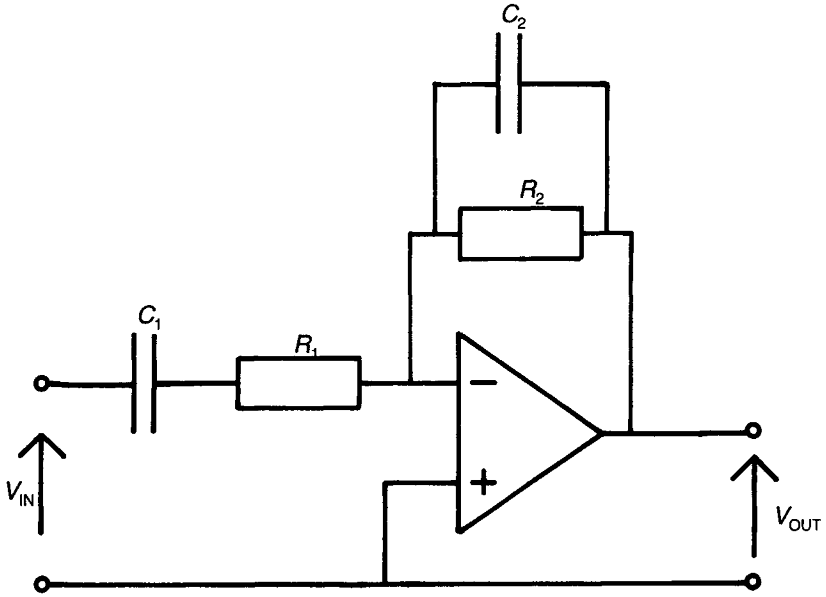

Figure 11.2 Inverting op-amp with restricted bandwidth

Non-inverting op-amp

Figure 11.3 shows a non-inverting op-amp circuit, in its most basic configuration. This circuit has a gain as follows:

$$A_V = \frac{R_1 + R_2}{R_1} \qquad (11.3)$$

This means that the circuit can only provide gain of greater than 1. Its input impedance is very large, and is not usually taken into account. As with the inverting op-amp, its output impedance is very low, with the same restrictions on output drive applying (Figure 11.4).

Where it is desired to restrict the bandwidth of the stage, capacitors C_1 and C_2 are added. The calculations are identical to those for the inverting stage. Note that with C_1 in this position the input signal must have some defined DC level. If the input is connected using a DC block capacitor then C_1 must be omitted so that the op-amp has a DC reference. If it is desired to limit the low frequency response of the stage it is sometimes better to connect the input via a suitable high-pass filter, as described in Chapter 9.

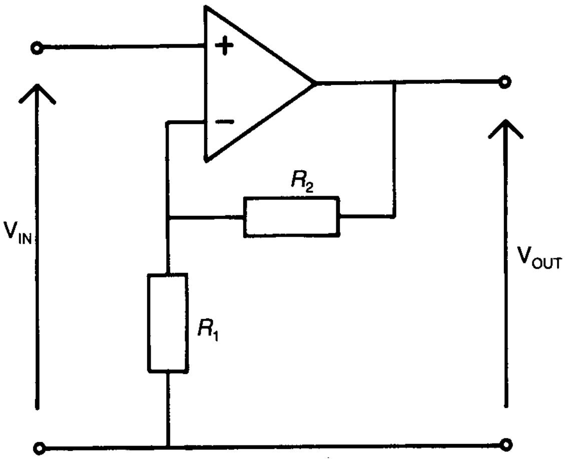

Figure 11.3 Non-inverting op-amp

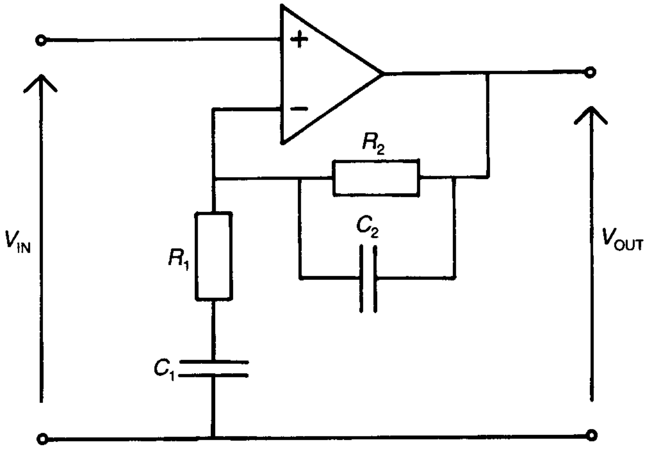

Figure 11.4 Non-inverting op-amp with restricted bandwidth

The main advantage of this stage (other than its being non-inverting) is that of its input impedance. It makes an ideal buffer stage, after circuits which are sensitive to load impedance (such as the reactive circuits described in Part Two).

Where it is desired to use this circuit without gain, purely as a buffer stage, it is customary to omit R_1 and make R_2 short circuit – i.e. to link the output terminal to the inverting input terminal, as in Figure 11.5. This is a 'voltage follower'. The output is identical to the input, but comes from a very low source impedance.

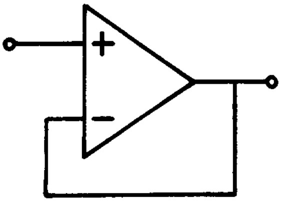

Figure 11.5 A voltage follower

Values for R_1 and R_2 for the non-inverting amplifier can be selected using Table 8.1, in the 'Voltage dividers' chapter. The dB column gives values of gain directly, and the A column values of the reciprocal of gain as a ratio. R_1 from the table should be fitted as position R_2 from Figure 11.3 and R_2 as R_1. As usual, R_1 and R_2 can be scaled by factors of 10 if desired.

Units, symbols and suffixes

I have used standard units, symbols and suffixes throughout this work. Here they are:

Units
Ω or R: ohms (resistance)
F: farads (capacitance)
H: henries (inductance)
s: seconds (time)
Hz: hertz (frequency)
°: degrees (phase angle)
V: volts (electrical potential)
A: amperes (electrical current)
W: watts (power)
J: joules (energy or work)

Symbols
R: resistance
C: capacitance
L: inductance
V: voltage
I: current
X_C: capacitive reactance
X_L: inductive reactance
Z: impedance
f: frequency
ϕ: phase angle
$\mathrm{f_O}$: resonant frequency
$\mathrm{Z_O}$: dynamic (resonant) impedance

Electronics engineers tend to deal in a very wide range of numbers, from million-millionths of farads to millions of ohms. Hence it is usual to use a range of letter suffixes to indicate the order of magnitude of a number.
These are the standard suffixes used in this book:
p: $\times 10^{-12}$
n: $\times 10^{-9}$
μ : $\times 10^{-6}$
m: $\times 10^{-3}$
k: $\times 10^{3}$
M: $\times 10^{6}$

So, for instance, $\frac{1\text{V}}{1\,\text{k}\Omega} = 1\text{m}A$; $1\text{M} \times 1\,\text{nF} = 1\text{ms}$; and so on.

Colour codes

The following colour codes are used on resistors, and sometimes on capacitors and inductors, to indicate value:
Number bands
Black 0
Brown 1
Red 2
Orange 3
Yellow 4
Green 5
Blue 6
Violet 7
Grey 8
White 9

Tolerance bands
Brown 1%
Red 2%
Gold 5%
Silver 10%

Figure A2 shows the significance of the bands for a resistor.

For example; a four band resistor with colours yellow–violet–red–red (the last one thick) is $47 \times 10^2 = 4\text{k}7$, 2%. A five band with brown–grey–black–brown–brown (again the last thick) is $180 \times 10 = 1\text{k}8$, 1%.

The decibel

The decibel, or dB, is a logarithmic unit for expressing ratios, much beloved of engineers. Its popularity is due to the fact that it enables a wide range of numbers to be expressed conveniently.

Where we are talking about a ratio of two voltages then:

$$dB = 20\,log_{10}\left(\frac{V1}{V2}\right) \tag{A3.1}$$

which means that 'A is twice B' is often expressed as 'A is 6dB greater than B', and 'A is ten times B' becomes 'A is 20dB up on B'. Gain or attenuation of circuit blocks are very well expressed like this (a negative gain is an attenuation, or a ratio of less than one). The ratio is 'output/input'.

dB's are also used to express signal levels a lot. Here some reference level should be stated to make the situation clear. The most common are:

$$\mathrm{dBV} = 20\log_{10}(\mathrm{V_{rms}}) - \text{reference to } 1\mathrm{V_{rms}}$$

$$\mathrm{dBu} = 20\log_{10}\left(\frac{\mathrm{V_{rms}}}{0.775}\right) - \text{reference to 1mW into 600 } \Omega$$

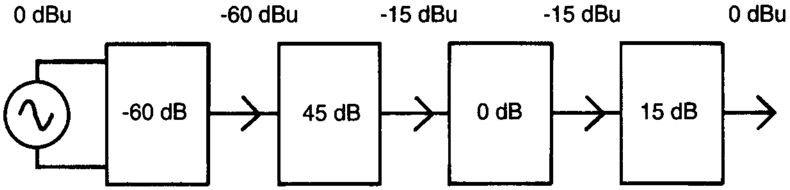
though you may very well come across others. Where there is doubt it is often wise to try to find out what reference was used, as it can be a source of confusion.

The beauty of this system is that the level of a signal at various point in a chain can be found just by adding the dB values together. See Figure A. 3. It is apparent that the calculation in dB's is trivial compared to that using V_{RMS} and gain/attenuation as ratios.

dB's are also used sometimes to express relative power. The equation then used is:

$$\mathrm{dB} = 10\log_{10}\left(\frac{P1}{P2}\right) \tag{A3.2}$$

This is because power varies proportionally to the square of voltage, as implied by Eqs 2.4d and 2.4e.



$$0.775\ \mathrm{V} \times \frac{1}{1000} = 0.775\ \mathrm{mV} \times 177.8 = 138\ \mathrm{mV} \times 1 = 138\ \mathrm{mV} \times 5.62 = 0.775\ \mathrm{V_{RMS}}$$

Complex number analysis

The standard way to analyse a circuit containing AC quantities at a fixed frequency is to use complex numbers. A complex number has two parts, real and imaginary. The imaginary part is some function of the quantity j (i to pure mathematicians, but that would be confused with current by us), where j represents $\sqrt{(-1)}$. This is clearly a 'nonsense number', or at least unquantifiable, yet it has some useful properties:

$$j^2 = -1 \tag{A4.1a}$$

$$j^3 = -j \tag{A4.1b}$$

$$j^4 = 1 \tag{A4.1c}$$

We use multiplication by j to signify advancing its phase by 90°. Complex numbers owe their usefulness to the fact that they can be seen as representations of phasors. For example:

$$V = a + jb$$

is a voltage which can be represented in the j-plane as in Figure A. 4.

This number could also be represented as 'magnitude and phase' (as in Chapter 4) by using some trigonometry:

$$M = \sqrt{a^2 + b^2} \tag{A4.2}$$

$$\phi = \arctan\left(\frac{b}{a}\right) \tag{A4.3}$$

Then we are able to write the phasor in polar form:

$$V = M < \phi$$

Should we wish to convert a quantity from polar to complex form we need a little more trigonometry:

$$a = M cos\phi \tag{A4.4}$$

$$b = M sin\phi \tag{A4.5}$$

Mathematical operations with complex numbers

We treat complex numbers like any other algebraic quantity, keeping the j part separate as we would with x or y, but also applying Eqs A4.1 as necessary. So:

$$\text{Addition} : (a + jb) + (c + jd) = (a + b) + j(c + d) \tag{A4.6}$$

$$\text{Subtraction} : (a + jb) - (c + jd) = (a - c) + j(b - d) \tag{A4.7}$$

$$\text{Multiplication} : (a + jb)(c + jd) = (ac - bd) + j(bc + ad) \tag{A4.8}$$

Division: a useful tool for separating fractions is multiplication by the 'complex conjugate', which makes the denominator wholly real:
as:

$$(c + jd)(c - jd) = c^2 + jcd - jcd - j^2d^2 = c^2 + d^2$$

then:

$$\frac{a + jb}{c + jd} = \frac{(a + jb)(c - jd)}{c^2 + d^2} \tag{A4.9}$$

However, multiplication and division are sometimes more easily performed by converting to polar form and then:

Multiplication in polar form:

$$M_1 < \phi_1 . M_2 < \phi_2 = M_1 M_2 < (\phi_1 + \phi_2) \tag{A4.10}$$

Division in polar form:

$$\frac{M_1 < \phi_1}{M_2 < \phi_2} = \frac{M_1}{M_2} < (\phi_1 - \phi_2) \tag{A4.11}$$

Representation of capacitors and inductors

Complex numbers come into their own when we use them to represent reactive components in equations. The impedance of a capacitor becomes:

$$X_C = \frac{-j}{2\pi f C} \tag{A4.12}$$

and an inductor:

$$X_L = j2\pi fL \tag{A4.13}$$

and all of the analysis techniques of Chapter 5 can be used, following the algebraic rules given above.

Further reading

Should the reader wish to gain greater understanding of any of the topics which this book touches on, I have found the following to be excellent:

Schuler, C. A. and Fowler, R. J. (1993) *Electric Circuit Analysis*, McGraw-Hill, London.
A clear and thorough explanation of circuit analysis techniques which also contains good chapters on electromagnetism and electrostatics.

Marston, R. (1993) *Electronic Circuits Pocket Book*, Vols One and Two, Butterworth-Heinemann, Oxford.
A comprehensive and informed circuit sourcebook that also analyses the ideas used in sufficient depth to make them really useful. Contains many useful circuits.

Horowitz, P. and Hill, W. (1989) *The Art of Electronics*, Cambridge University Press, Cambridge.
Deservedly considered to be the classic all-round electronics text. Clear, concise and entertaining too.

Phillips, G. (1993) *Newnes Electronics Toolkit*, Butterworth-Heinemann, Oxford.
A great deal of useful information in a small space; an ideal source of reference for the workshop or lab.

Editorial

There are many and varied good reasons for building a project from plans published in a magazine. I won't go into listing all these reasons because I would probably leave your motivation off the list. Now then, can you think of one bad reason for building a project from a magazine plans? Think about it.

I find that too many project builders follow the plans scrupulously, not varying from the schematic diagram. They even produce a project that mirrors the photographs supplied in the construction article. Admittedly, editors prefer that readers build projects than not. Albeit, why not show some creativity. Every project can be improved upon in some way. A cosmetic change to suit your fancy may not be an electronic-design advancement, but it does show some individualism.

To encourage the builder's development of published instruction articles, the editors decided to publish The Project Anthology that appears in the center of this magazine. This Anthology is a Lilliputian compilation of varied projects that are bound to excite the builder into assembling more than one of them. Since the complete plans are not provided (in most cases only schematic diagrams and parts lists are provided), the plans leave the final assembly design up to the builder. Also, the circuits themselves are simple enough so that the introduction of new electronic design features can be added.

What the editors are attempting to do is promote your sculpturing of the project to suit on-site needs. We want you to build what you need from our plans. The foray into designing circuits eventually becomes habitual and rewarding.

Who knows! You may become one of our authors when your projects are designed from your original plans!

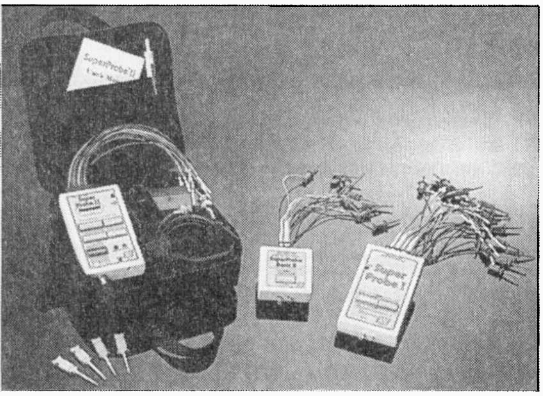
OSCILLOSCOPE TRIGGER DEVICES

THE SUPERPROBE OSCILLOSCOPE triggering devices from Programmable Designs are instruments that can trigger complex events in digital circuitry and simplify circuit debugging and testing. They will work with any oscilloscope to provide a wide range of event-triggering options. Four different models are available.

The SuperProbe II has 18 digital logic inputs and a clock input. It supports three clocked triggering modes and one combinatorial (pattern-match) triggering mode. The device works with flexible logic combinations for specifying triggering events. These include no-match triggering for triggering when certain unexpected events occur. This model has separate "pattern select" and "don't care" configuration DIP switches.



CIRCLE 60 ON FREE INFORMATION CARD

Status LEDs permit the monitoring of power, input signals, triggering activity, and clock activity. This instrument includes an interface cable assembly with removable grabbers and gold-plated machined contacts that work with IC clips and 0.025-inch posts.

SuperProbe I is a pattern-match or word-recognition version with 17 digital inputs. It allows any logical combination with up to 17 signals to be specified for the trigger event. This model is offered in two versions. The standard version includes an interface cable with permanently attached grabbers for through-hole component leads. The deluxe version has a cable identical to the one included with the SuperProbe II.

The SuperProbe Basic-8 permits pattern-match triggering with up to eight signal inputs. It includes a cable with permanently attached through-hole component grabbers.

SuperProbe pricing ranges from $99.00 to $549.00, depending on the model.

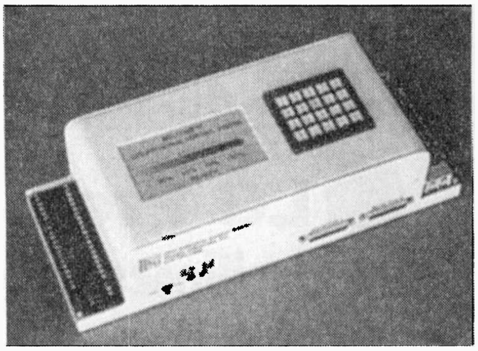
INDUSTRIAL CONTROL SYSTEM

THE QED INDUSTRIAL Control System (ICS) from Mosaic Industries is a single-board computer with either a character or graphics LCD display, and a keypad or touchscreen. It has a battery-backed memory, real time clock, analog and digital I/O, board area for prototyping, and provision for serial communications. The system is packaged in an industrial-style enclosure with screw-terminal connections.

This packaged system is intended for many different applications including machine automation, data acquisition, and robotics. The ICS can interpret data from temperature, pressure, and optical sensors; process the input data; and control stepper motors, valves, relays, and other actuators.



CIRCLE 37 ON FREE INFORMATION CARD

Palm-sized plug-in cards introduce isolated high-current outputs and high-voltage inputs, 4 to 20-milliampere signalling, and analog-to-digital or digital-to-analog conversions. The system modules can be programmed in C or Forth from a personal computer with on-board multitasking software.

The QED Industrial Control System with character display and keypad (ICS-AK) is priced at $995.00. With a graphics display and keypad (ICS-GK), it is priced at $1190.00.

The LM2406T can drive a cathode capacitance of 8 pF with a voltage swing of 40 volts peak-to-peak, and it has a rise and fall time of 9 nanoseconds. When paired with National Semiconductor's LM1203N or LM1207N video amplifiers, the combination forms a complete video channel for SVGA and XGA computer monitors.

The monolithic IC includes internal protection to prevent momentary short circuiting. It reduces monitor component count, simplifies system design and manufacture, and increases system reliability .It is offered in a reduced-size TO-220 package.

The LM2406T monolithic CRT driver is priced at $2.50 in quantities of 1000.

MULTIMETER WITH CLAMP-ON ADAPTER

THE AMPROBE MODEL PMM-1 is designed so that a clamp-on adapter can be connected, allowing it to measure up to 300 amperes. The basic DMM is a 3200-count instrument that measures AC and DC voltage to 600 volts and ohms to 30 megohms. It has an annunciated LCD readoutand a 65-segment analog bargraph,. The DMM offers auto and manual ranging, audible continuity testing and data hold. It also performs diode checks The PMM-1 has 600-volt AC and DC protection on all ranges.

With the addition of the PMM-C clamp-on adapter, the PMM-1 can measure up to 300 amperes AC. The adapter jaws will close over conductors up to 1.14-inch in diameter. The combination has an output of 1 millivolt AC per 0.1-ampere AC. With additional optional accessories, thePMM can do infrared scanning and measure up to 1000 amperes AC, 600 amperes DC, temperature, and up to 400 kilowatts.

The PMM-1 digital multimeter with carrying case, test leads, batteries, and a user's manual is priced at $69.85. The PMM-C clamp-on accessory is priced at $49.85.

COMPUTER CARD FOR MULTIMEDIA PRESENTATIONS.

THE MODEL ME1000 (VGA2-NTSC) plug-in computer card from Methode Electronics allows multimedia presentations to be displayed on a standard television receiver or recorded on a VCR. The card converts VGA computer graphics, computer-aided designs, and multimedia presentations to standard NTSC video output.

The card automatically detects and switches between 640×480 pixel, 320×200 pixel, and 80-column text modes. The plug-in card works with any IBM or compatible personal computer that has an Intel 386, 486, or Pentium processor , an ISA bus, and a graphics card with the appropriate connector.

The ME1000 also provides flicker-free images, CAD-drawing output with no missing lines, and sharp 80-column text mode. The card conforms to multimedia standards, and it is compatible with AutoCAD and 3D Studio CAD software. It is also compatible with DOS and Windows operating systems. The cards can display 256 colors and are easily installed with the included internal cable.

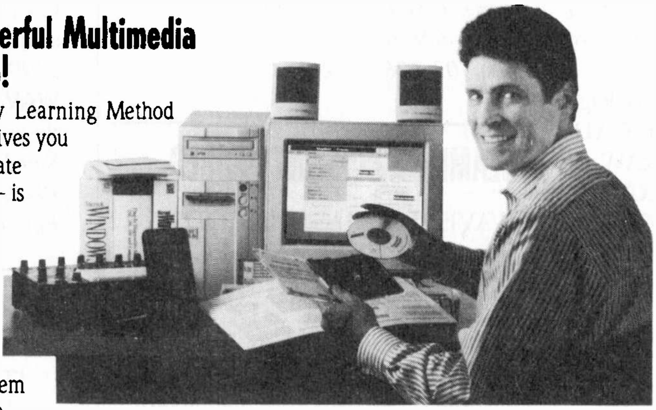
Thousands of Successful Graduates Are Proof That NRI Computer Repair Training Works!

NEW! Course Includes Powerful Multimedia Computer and Windows 95!



NRI's highly acclaimed Discovery Learning Method – the learn-by-doing approach that gives you first-hand experience with the intricate electronics behind microcomputers – is the most effective way to learn a new skill. You start with NRI's Discovery Lab – a complete breadboarding system that lets you design circuits, modify them, and then diagnose and repair faults.

You then go on to explore and test a state-of-the-art 486DX4/100 MHz computer. This powerful MPC2 system now boasts these exciting features:

- 8 meg RAM
- 128K cache memory
- 540 meg hard drive
- Super VGA color monitor
- 14,400 baud fax/modem
- Quad-speed CD-ROM drive
- 16-bit sound card

> ***"Just two years after finishing the NRI training in microcomputer servicing, I set up my own company. I contract myself out to several computer retailers as their service technician. I have control over my future and total confidence in my business."***
>
> **V. Bender, Calgary, Alberta**

What's more, you perform diagnostic tests using the professional-level Ultra-X R.A.C.E.R. II plug-in card and QuickTech-PRO software, all included in your course.

Plus, NRI training now includes Windows 95, the graphical user interface that's taken the computing world by storm.

Train in the Privacy of Your Own Home

No prior experience necessary – with your personal instructor and NRI's team of technical specialists behind you every step of the way, you learn at your own pace. No classroom pressures, no night school, no need to quit your present job until you're ready to make your move.

Take Advantage of Today's Money-Making Opportunities in Computer Repair

The Department of Labor forecasts over 220,000 jobs for computer service technicians by the year 2005. With the right training and skills, you can cash in on this wide-open opportunity. Only NRI prepares you so thoroughly for a full- or part-time job as a computer service technician – even a business of your own!

> ***"I recommend NRI to anyone looking for a change, success, and real challenge. Hands-on projects allow you to build on what you studied in the lessons – no better way exists to learn how to troubleshoot and service computers!"***

boards to 0.00025-inch resolution for short-production runs or prototyping. It can also mill circuit patterns and machine complex three-dimensional objects from plastic, aluminum, brass, wood, or modeling wax.

The worktable for the AccuMILL/Plus measures 10×14-inches. Its automated tool carousel has eight tool motors. These include one fully automatic, fixed/floating position for accurate milling of irregular surfaces. Adjustments can be made to 0.001 inch. The machine has three different motor speeds: 7000, 28,000, or 50,000 rpm. Three-axis mounting of the tools permits the fabrication of three-dimensional parts.

The AccuMILL software package is compatible with AutoCAD, AutoSKETCH, and CorelDRAW. It can interpret ASCII and HPLG plotter-files running under MS-Windows. The AccuSTEPPER controller is an automated computer interface that controls all three axes.

The AccuMILL/Plus desktop machining center is priced at costs xx.

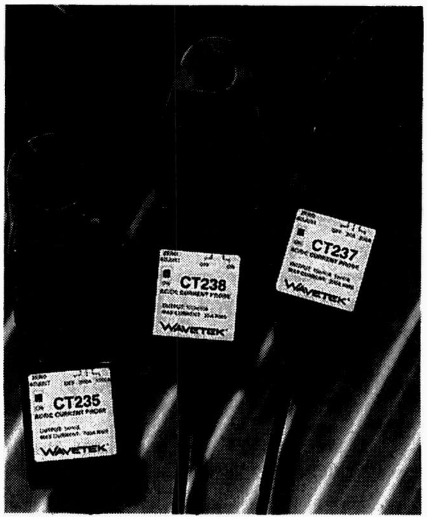
CLAMP-ON CURRENT PROBES

WAVETEK HAS INTRODUCed its CT235, CT237, and CT238 AC/DC clamp-on current probes that will measure AC or DC current noninvasively from 5 milliamperes to 1000 amperes peak with 1% accuracy. The broad AC bandwidth and 1% accuracy of the probes permit the precise measurement of complex waveforms distorted by harmonics or power-line anomalies.

The current probes can be used with different test instruments including analog or digital multimeters, dataloggers, chart recorders, and power analyzers. Current measurements are obtained with Hall-effect sensing, and the zero-adjust feature cancels residual magnetic fields, so DC measurement accuracy is unaffected.



CIRCLE 46 ON FREE INFORMATION CARD

Applications for the probes include the analysis of current waveforms for harmonics, the testing of banks of batteries, the analysis of inverter power output, the recording of UPS charge and discharge rates, and the diagnosis of automotive electrical systems. The probes have IEC1010-1, Category III, 300-volt, pollution degree 2 safety approval.

The pricing on the probes is: CT235 (1000-ampere)—$179.00; CT237 (200-ampere)—$249.00, and the CT238 (20-ampere)—$299.00

DIRECT DIGITAL SYNTHESIZER MODULE

THE MODEL DDS4M DIRECT digital synthesizer (DDS) module from Novatech Instruments generates a precise sinewave and an accurate TTL clock signal. It is packaged on a 3.5×4.5-inch circuit board. The output frequency is programmable from 1 Hz up to a maximum of 34 MHz in steps as small as 0.02 Hz.

The typical phase noise for the module is −i90 dBc at 1-kHz offset from carrier. The desired frequency can be selected by setting a 31-bit binary number, either manually with DIP switches or remotely with HCMOS-compatible parallel input lines. The DDS4m contains a quartz crystal oscillator that provides stability of 10-ppm/year.

TIPS FOR MAIL ORDER PURCHASE

It is impossible for us to verify the claims of advertisers, including but not limited to product availability, credibility, reliability and existence of warranties. The following information is provided as a service for your protection. It is not intended to constitute legal advice and readers are advised to obtain independent advice on how to best protect their own interests based upon their individual circumstances and jurisdictions.

1. **Confirm price and merchandise information** with the seller, including brand, model, color or finish, accessories and rebates included in the price.

2. **Understand the seller's return and/or refund policy**, including the allowable return period, who pays the postage for returned merchandise and whether there is any "restocking" or "return" charge.

3. **Understand the product's warranty.** Is there a manufacturer's warranty, and if so, is it for a U.S. or foreign manufacturer? Note that many manufacturers assert that, even if the product comes with a U.S. manufacturer's warranty, if you purchase from an unauthorized dealer, you are not covered by the manufacturer's warranty. If in doubt, contact the manufacturer directly. In addition to, or instead of the manufacturer's warranty, the seller may offer its own warranty. In either case, what is covered by warranty, how long is the warranty period, where will the product be serviced, is there a charge for service, what do you have to do to obtain service and will the product be repaired or replaced? You may want to receive a copy of the written warranty before placing your order.

4. **Keep a copy of all transactions**, including but not limited to cancelled check, receipt and correspondence. For phone orders, make a note of the order including merchandise ordered, price, order date, expected delivery date and salesperson's name.

5. **If the merchandise is not shipped within the promised time**, or if no time was promised, within 30 days of receipt of the order, you generally have the right to cancel the order and get a refund.

6. **Merchandise substitution** without your express prior consent is generally not allowed.

7. **If you have a problem with your order or the merchandise**, write a letter to the seller with all the pertinent information and keep a copy.

8. **If you are unable to obtain satisfaction from the seller**, contact the consumer protection agency in the seller's state and your local Post Office.

If, after following the guidelines, you experience a problem with a mail order advertiser that you are unable to resolve, please let us know. Write to Advertising Department, Gernsback Publications Inc., 500B Bi-County Blvd. Farmingdale, NY 11735.

Be sure to include copies of all correspondence.

exceed those of fuses. Under fault conditions, the UCC3913 devices quickly limit overcurrent, preventing damage to host circuitry. They open the circuit automatically and reset with a 2% duty cycle to limit power dissipation during extended-duration faults.

An automatic reset feature reduces field maintenance. The auto-reset feature also prevents overheating that could lead to circuit failure. The UCC3913 devices manage power by permitting full logic control of each module's power. Their programmable start delays are especially important in "hot-swap" situations such as when power supply modules are being replaced in fault-tolerant computer systems.

The electronic circuit breakers keep the power off, then "soft-start" the module in hot-swap applications. That controlled start prevents the module from excessively loading the bus as it powers up, preventing power and data glitches. The UCC3913 family is offered in eight-pin SOIC and DIP packages in three temperature ranges.

The UCC3913 is priced at $1.40 in 1000-piece quantities.EP

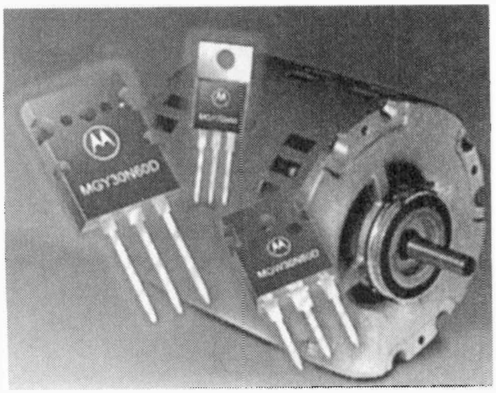
INSULATED-GATE BIPOLAR TRANSISTORS

A NEW SERIES OF 600- AND 1200-volt insulated-gate bipolar transistors (IGBTs) for high-voltage applications has been announced by Motorola. The high-voltage IGBTs are optimized to operate efficiently from full-wave rectified 230- or 460-volt AC with minimum conduction and turn-off losses. The IGBTs will withstand a short circuit for a minimum duration of 10 microseconds.

The IGBTs are suitable as inverters for motor drives. They perform the power-switching function that converts rectified DC line voltage to pulses that permit the control of various kinds of motors. IGBTs can also function in uninterruptible power supplies and conventional switching power supplies operating directly off line at moderate frequencies.



CIRCLE 41 ON FREE INFORMATION CARD

For applications where the stored energy of an inductive load is returned back to the power source through a diode, IGBTs and fast-recovery diodes have been co-packaged. The fast-recovery diode is connected anti-parallel to the IGBT to allow reverse conduction. That permits the return of energy stored in an inductive load to the power source in bridge circuits.

The reverse characteristics of the anti-parallel diodes have been designed to achieve "soft recovery" to minimize transients and EMI. The co-packaged diode minimizes transient voltages that are generated by stray circuit inductance. For applications where the anti-parallel diode is not needed, IGBTs without the diode are available at a slightly lower price.

The high-voltage IGBTs are priced in the range of $4.50 to $6.00 each in 100 to 999 quantity.

Mail-order distributor Digi-Key offers more than 1400 new products from 15 different manufacturers in its latest catalog. Newly introduced products include ribbon-cable and D-type subminiature connectors from AMP, Inc., power supplies from Power-One, microcontrollers from Microchip, and development systems from Picmaster.

A Quick Index on the first page will speed up finding references to the products being offered. This is supplemented by detailed manufacturer and product indexes. Digi-Key sells just about everything a manufacturer or serious electronic hobbyist needs and its catalog is a valuable reference for the professional designer as well as all advanced hobbyists.

The catalog is arranged alphabetically by manufacturer with alphabetical tabs on the outside edges of the pages for quick reference. A comprehensive index both by product and by manufacturer makes it easy to find what you are looking for in this huge 368-page compendium of electronic parts.

Digi-Key's product line card includes all the basic passive electronic components, discrete and integrated semiconductor devices, and connectors and cable assemblies and much more. The company offers hand tools, soldering materials, power supplies, and a wide variety of test equipment in addition to all the active and passive component lines that it lists.

This is a revised edition of Motorola's Hipercomm Databook. It contains device specifications in the form of data sheets and applications information for Motorola's frequency-control products. It contains technical data on a broad line of integrated circuits for phase-locked loop circuits. An introductory section simplifies the selection of the right components for a given set of applications requirements.

Motorola's line of low-power prescalers includes products with more than 40 different combinations of frequency, divide ratio, and power to meet the needs of most designs. Information is also included on Motorola's integrated, single-chip synthesizers that conserve power, making them suitable for handheld, battery-operated communications products.

This is the third volume of three in a series on QRP, an international radio Q signal that means "reduce your power". Previous titles were "QRP Basics" and "Advanced QRP Operating." This book on low-power communications examines the new and used equipment available for the radio amateur who is planning to upgrade a QRP station that might be communicating with microwatts of power. It includes tips on buying and trading used equipment, and discusses operating accessories of value to the QRP operator.

This book is a complete design guide for printed and LC filters for RF and microwave applications. It includes easy to understand discussions of high-frequency filter theory and accurate computer simulation models for many different filters. Rhea's book includes a review of the classic design formulas as well as the more recent filter design concepts developments.

The first chapters are devoted to fundamental concepts, with greater emphasis given to lumped-elements than distributed elements. Those chapters are followed by a review of available computer-aided filter-design techniques, including both simulation and synthesis.

The author goes on to discuss distributed low-pass, bandpass, high-pass, and bandstop filters, and he explains how to select the appropriate design for specific applications.

CUSTOM METER FACES

Customize analog meter faces with your PC and a laser printer.

SKIP WITHROW, WB0BBE

EVEN IN TODAY'S WORLD OF DIGITAL electronics there are still times when an analog meter is the better choice for displaying voltage, current, or other signal levels. With the use of a personal computer and a laser printer, this article shows how you can customize analog meters from your junk box or local surplus dealer to display almost any scale and units. Gone are the days of trying to draw meter scales by hand; you can make your computer and laser printer do the work for you.

Any laser printer that understands HPGL (Hewlett-Packard Graphics Language) commands is compatible with the techniques presented here. The BASIC programming language is used to assemble the commands which are then sent to the printer. The printer prints the new scale on a whole-page laser label and then the label is applied to the old meter. Figure 1 shows a meter, purchased for $2 at a surplus electronics outlet, before and after modification.

Finding the right meter

The first step to successfully making a newly labeled meter is to start with the right meter. Although many meters can be found for very reasonable prices in the surplus market, not every meter is a candidate for a new scale. Several specifications, such as the full-scale current and the meter movement's resistance, are helpful in determining whether the meter is a suitable choice.

To change the scale of a meter, the face must be accessible. Some inexpensive meter movements have cases that can't be opened, and these should be avoided. Generally the cover of a meter face can either be removed by simply prying it off, or by removing several small screws on the outside of the meter. The second task is to remove the meter face itself. Again, some inexpensive meters might have their faces mounted permanently, but the majority of meters have several small screws that hold the meter face in place. The ability to remove the meter face is essential.

Other things that must be known about the meter before it can be used in a circuit properly are its full-scale current and the resistance of its movement coil. For a new meter, these are easy to determine from the meter's specification sheet. Sometimes you will be lucky enough to find information printed on an old meter face that will help determine the full-scale reading.

If you know nothing about a meter's electrical specifications, they can be determined rather easily. Generally most meters have a full-scale current between 100 microamperes and 1 milliampere. Coil resistance generally varies between about 40 and 1000 ohms. The setup to measure full scale current and coil resistance is simple. The value of the power supply is not critical. A potentiometer between the supply and the unknown meter should be large enough to limit current to about 50 microamperes (about 200K). First set the potentiometer to its maximum value, turn on the power supply, then decrease the resistance until the meter reads full scale. Measure

Graduate with an Associate Degree from CIE!

CIE INSTITUTE OF ELECTRONICS · 1934 ·

CIE is the best educational value you can receive if you want to learn about electronics, and earn a good income with that knowledge. CIE's reputation as the world leader in home study electronics is based solely on the success of our graduates. And we've earned our reputation with an unconditional commitment to provide our students with the very best electronics training.

Just ask any of the 150,000-plus graduates of the Cleveland Institute of Electronics who are working in high-paying positions with aerospace, computer, medical, automotive and communications firms throughout the world. They'll tell you success didn't come easy...but it did come...thanks to their CIE training. And today, a career in electronics offers more rewards than ever before.

CIE'S COMMITTED TO BEING THE BEST...IN ONE AREA...ELECTRONICS.
CIE isn't another be-everything-to-everyone school. CIE teaches only one subject and we believe we're the best at what we do. Also, CIE is accredited by the National Home Study Council. And with more than 1,000 graduates each year, we're the largest home study school specializing exclusively in electronics. CIE has been training career-minded students for nearly sixty years and we're the best at our subject... ELECTRONICS... IT'S THE ONLY SUBJECT WE TEACH!

CIE PROVIDES A LEARNING METHOD SO GOOD IT'S PATENTED.
CIE's AUTO-PROGRAMMED® lessons are a proven learning method for building valuable electronics career skills. Each lesson is designed to take you step-by-step and principle-by-principle. And while all of CIE's lessons are designed for independent study, CIE's instructors are personally available to assist you with just a toll free call. The result is practical training... the kind of experience you can put to work in today's marketplace.

LEARN BY DOING...WITH STATE-OF-THE-ART EQUIPMENT AND TRAINING.
CIE pioneered the first Electronics Laboratory Course and the first Microprocessor • Course. Today, no other home study school can match CIE's state-of-the-art equipment and training. And all your laboratory equipment, books and lessons are included in your tuition. It's all yours to use while you study and for on-the-job after you graduate.

PERSONALIZED TRAINING....TO MATCH YOUR BACKGROUND.
While some of our students have a working knowledge of electronics others are just starting out. That's why CIE has developed twelve career courses and an A.A.S. Degree program to choose from. So, even if you're not sure which electronics career is best for you, CIE can get you started with core lessons applicable to all areas in electronics. And every CIE Course earns credit towards the completion of your Associate in Applied Science Degree. So you can work toward your degree in stages or as fast as you wish. In fact, CIE is the only school that actually rewards you for fast study, which can save you money.

the voltage of the supply and the value of the variable resistance. The voltage divided by the resistance will then give you the current required to deflect the meter full scale.

Another potentiometer can determine the meter coil resistance. With the meter indicating full-scale current, place a 1K potentiometer across the meter and adjust until the meter reads exactly ½ scale. Remove this potentiometer and measure its value. This will be the value of the coil resistance of the meter. The meter in Fig. 1 had a full-scale current reading of 229 microamperes and a coil resistance of 819 ohms.

Making faces

A protractor is the best tool for measuring the total angle of movement of the meter needle, which generally runs from 90 to 120 degrees. Also measure the distance from the pivot point to the scale of the old meter face and the location of the faceplate mounting holes with respect to the pivot point. Those measurements will be input to the program that draws the new meter face.

The next step in putting a new face on your meter is to carefully remove the old meter face plate. After opening up the meter case it is usually just a matter of removing the small screws holding the face plage on. A set of jeweler's screw drivers can sometimes be helpful for particularly small meters. Once the face plate is loose it can be removed by very carefully sliding it from under the needle of the meter. Be careful not to bend or bump the needle.

Using HPGL

HPGL is a graphics language of short, simple statements that allows lines, arcs, and text to be drawn. Originally developed for plotters, this language has been incorporated into many of today's laser printers. By using just a few of the many HPGL statements, professional looking meter scales can be created with customized features.

The BASIC language can send HPGL commands to the printer for drawing the various features of the scale. Using a computer language to send the commands to the printer is helpful because many commands can be generated using program loops with an incrementing variable. This lets rather short programs generate many different individual graphic elements to compose the new meter face plate.

Listing 1 is the BASIC program that draws the meter face in Fig. 2. Only a few of the many HPGL commands are used in the program. Most are two-letter commands followed by arguments. In Listing 1 many of the arguments are calculated by the BASIC program. The program plots points on a graph that has

The syntax of those commands is explained in the technical reference section for the HPGL language in your printer manual. Since some commands take X and Y coordinate locations, some simple trigonometry is used to calculate the arguments from the index angle in the program of Listing 1.

Developing your own meter face is a simple matter of running the program and printing the resulting graphics on the printer. You probably won't get it right the first time, but making modifications is easy. Writing the program in blocks that add a new graphic after each iteration works best. Printing locating marks on the new face for the mounting holes helps to align the new face properly on the old face plate.

Once everything looks the way you want it to on paper, print the results on a full-page laser label. It's best to apply the new label on the reverse side of the old face plate since it's usually a nice clean surface. Punch pinholes in the location marks to help locate them from the back side of the label. Peel off the backing of the new scale label and place the label face down. Then stick the face plate to the label, lining up the locator holes in the center of the face plate mounting holes. After applying the label use a modeling knife to trim the excess paper from around the meter face plate and mounting holes. Figure 3 shows the new label applied to the old meter.

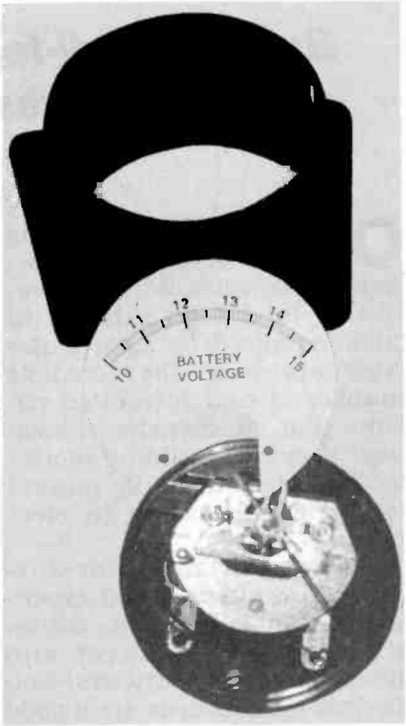

FIG.3—HERE IS THE NEW LABEL pasted onto the surplus meter.

Reassembly finishes the job. Carefully slide the face plate under the meter needle and replace the mounting screws. Next, replace the meter cover.

Creativity is the key to adding an exciting meter display to your next project. Expanded-scale voltmeters are an ideal application for this technique. Power supply current meters are also nice to have. This technique can also create non-linear meter scales such as decibel meters for audio or RF applications. Meter recycling can enhance your projects with just a small investment in time. Ω

PROTOTYPING STATION

Build this full-featured breadboard laboratory, and add custom features to suit your own needs.

One of the most gratifying benefits of being an electronics hobbyist is the opportunity to design and build custom projects for a particular need or purpose. The incredible number of new integrated circuits that are introduced each uear provides building blocks for circuits and fertile ground for experimentation in electronics.

One requirement for successful prototyping and experimentation is a quick, convenient way to connect and disconnect components. Solderless breadboards are a good start, but all too often one is likely to end up with the board in the center surrounded by a maze of wires that connect switches, potentiometers, meters, power supplies, and any number of other components that dangle in all directions. The arrangement of components can be both frustrating and irritating. The solution is to combine the breadboard, power supply, and other commonly used parts into a self-contained unit.

Factory-made laboratories like that are available, but they can be quite expensive. The lab described in this article, however, combines economy, expansion, and easy customization—you can use many of the parts you might already have on hand in your junkbox.

Design

The prototyping station base consists of a 20-inch length of 1- by 12-inch pine board that is sanded, stained and finished. The various power supplies are located to the right; the center section is reserved for three breadboards and the main equipment backboard. The left side is left open to accommodate additional modular backboards, or any other peripherals such as keypads or data-entry terminals. The base can be raised to make room for plastic drawers, power transformers, or other equipment. Rubber feet can be used to ensure that the lab is stable on the bench. That basic layout is shown in Fig. 1.

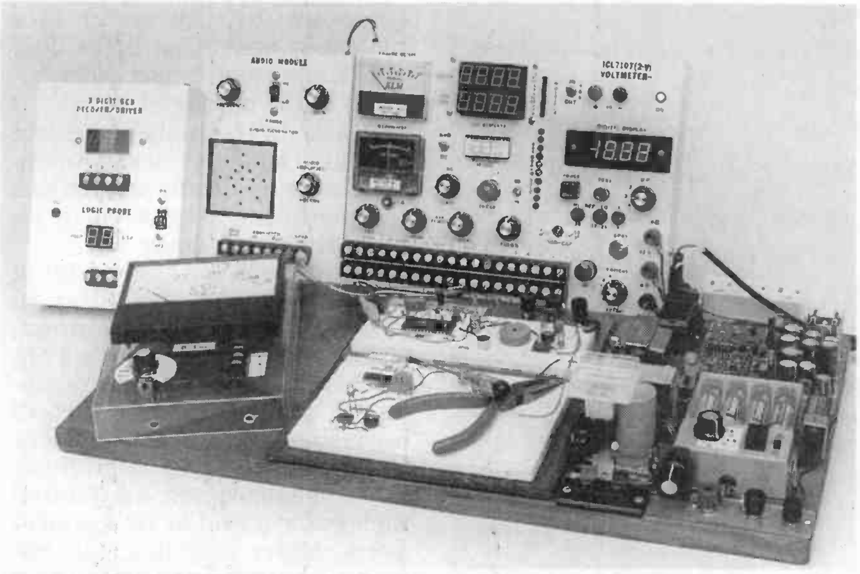

FIG. 1—BASIC PROTOTYPING LAYOUT. The base can be raised to make room for plastic drawers, power transformers, or other equipment.

Power supplies

Since the availability of power is always a requirement for successful prototyping, a variety of different power sources is incorporated on the right-hand section of the station (Fig. 2 shows a close-up view of the power section). The first power supply on the upper left is a surplus Texas Instruments computer board, bought at a clearance sale for $5. With the addition of an LED indicator, it provides a good clean source of ±5 volts and +12 volts. Being a computer-grade supply, the outputs are well-regulated, well-filtered, and can output about 1 ampere each. Power for this supply comes from an off-board wall-outlet transformer, and it is input to the supply via a two-position pushbutton terminal (the kind you might see on the back of a speaker).

Since a standard dry cell is appropriate to power many circuits, the second supply shown on the upper right of Fig. 2 consists of four AA cells and one 9-volt battery. The case from an old nickel-cadmium battery charger holds the AA cells, and a rotary switch and power indicator were added. The battery holder is tapped at each of the four positive battery pads, and each pad is wired to one pole of the rotary switch. The 9-volt battery is wired to a fifth pole on the rotary switch. This allows the selection of 1.5, 3, 4.5, or 6 volts DC from the AA pack, and

9 volts from the 9-volt battery. The LED indicator is a 0.3-inch high, seven-segment display, with all segments turned on to form an "8," which is a more noticeable reminder of the "on" status of the battery pack than a single LED. The output from this supply is connected to two of three binding posts for easy access. The third binding post is the negative 5-volt supply from the TI computer supply.

Another voltage source is provided by a +1.2- to 20-volt DC variable power supply that was built from a kit some years ago. The potentiometer next to the battery pack allows for adjustment of the output voltage, which is available at another two-position pushbutton terminal. An analog meter indicates the voltage at the pushbutton terminals.

Next to the variable supply is a 12.6-volt, center-tapped transformer, complete with a switch and indicator LED, that provides 6- and 12-volts AC. An SPST slide switch is connected to one side of the 120-volt AC input to the transformer primary. The outputs are wired to multipurpose posts on the main backboard.

AC power is made available at a triple-outlet AC strip, which gets its power via a heavy-duty line cord. The power inputs for the AC and variable supplies are also connected to this line cord.

The five separate power supplies can be customized to suit your needs. If you decide to enclose the power supplies, be sure to provide for adequate ventilation to allow heat to escape. The main 120-volt AC input should be protected against surges and spikes if you anticipate prototyping computer circuits.

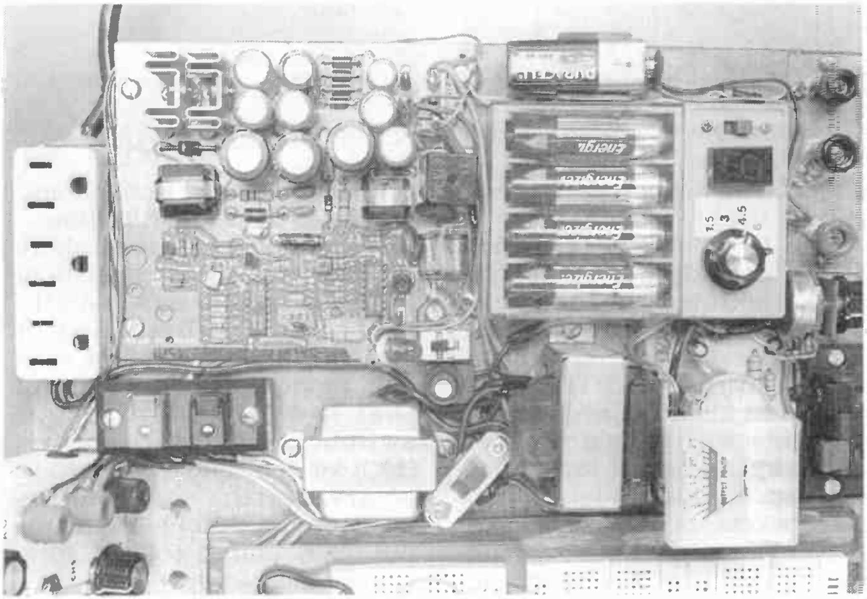

FIG. 2—A VARIETY OF POWER SOURCES is incorporated into the lab.

Breadboards

In the center of the base board are three 640-point solderless breadboards, laid out side-by-side (see Fig. 3). The top breadboard is a Radio Shack unit on a metal base with three multipurpose posts. The other two breadboards are plug-in panels mounted on a plywood base. All three breadboards have dual two-connection bus lines at their tops and bottoms, and will accommodate SIPs, DIPs, dis-

crete components, and jumper wires. While this breadboard arrangement has provided the author with enough space and has been versatile enough for all of his projects to date, it is certainly not the only arrangement possible. The breadboards are available in a variety of shapes and sizes, with from 250 contact points to 2500 or more. Some thought about the types of circuits you'll be working on will help you make a final decision on this part of the lab.

Backboards and modules

The main function of the backboard is to support more cumbersome components, modules, and any other circuits that the builder wants to add—items such as switches, potentiometers, meters, displays. The main backboard occupies about 10 inches across the back edge of the base (see Fig. 4).

Two 19-position terminal strips provide access to the parts mounted on the backboard. The strips on the prototype were removed from a surplus alarm board. The screw terminals allow connections to be made with alligator clips, bare wire, and spade lugs. However, spring-loaded terminals, SIP sockets, or any other connector you might have on hand can be used here. Each point on the terminal strips is wired to a connection on the component, and labeled for identification.

The row of components above the terminal strips consists of four potentiometers (1-, 10-, and 100-kilohms and 1 megohm) and a 4- to 55-pF variable capacitor. To the right of that row is a DPDT toggle switch, momentary control (MC) switch, and six-position rotary switch. The binding posts on the extreme right output the 6- and 12-volts AC, previously mentioned.

On the left side are two analog

meters (M1 and M2). Meter M1 is rated for 0 to 1 milliampere, which is a useful value for many circuit designs, and M2 is 500 microampere, ± center scale unit. This is essential when designing a circuit where the output can swing either positive or negative. Meter M2 is illuminated, and the small push-button switch labeled L.O. activates the 6-volt lamp.

A bank of seven-segment LED displays is mounted in the top center of the backboard. The first row of four is in a multiplexed arrangement, with all like segments tied together. Connection to the multiplexed displays is accomplished via the SIP socket to the right, which is labeled accordingly. The second row of seven-segment displays is wired as a 3½-digit display that allows individual access to each of the 24 segments and the common anode. Connections to this display row are made via the DIP socket below it, which is marked appropriately for use with digital circuits having that type of output.

Below the DIP socket is an incandescent lamp indicator with a bayonet-type socket. Bulbs are easily changed, and they are available in 6-, 12-, 14-, and 28-volt versions.

The author installed a ten-step LED bargraph and a 3½-digit voltmeter on the backboard, both as a matter of personal preference. The bargraph is mounted in the center of the backboard as shown in Fig. 5. A schematic of the LED bargraph circuit is shown in Fig. 6. The circuit consists mainly of an LM3914 bargraph display driver IC. Switch S1 allows signals to be input to the driver chip

Signals are input to the bargraph circuit at J1, a ⅛-inch mini phono jack. The 5-kilohm potentiometer (R2) controls gain. The author used a potentiometer with a built-in on/off switch so that power to the bargraph display could be turned on and off independently. You can either do the same, or use a separate switch for power. Power for the bargraph circuit is provided by the TI computer supply.

Build this simple superheterodyne receiver to receive time and other useful signals from NIST's WWV and WWVH.

WWV RECEIVER

NEIL HECKT

BROADCASTING THE EXACT TIME OF day is just one of the many services provided by radio stations WWV and WWVH operated by the National Institute of Standards and Technology (NIST). Their ultra-accurate 10-megahertz carrier frequencies can be used to calibrate signal generators in a process called "zero beating" against the carrier frequency. The stations also transmit many other accurate frequencies, storm warnings for mariners at sea, and GPS (Global Positioning Satellite) position data.

This article explains how to build a simple, inexpensive superheterodyne radio receiver for WWV and WWVH signals. The objective in the design of this receiver was to obtain reliable reception with an antenna only 3- to 6-feet long. The sensitivity obtained with this receiver equals that obtainable from a $1000 communications receiver operating from a 60-foot antenna.

Can the performance of a receiver made from $30 worth of parts equal the performance of a $1000 factory-built receiver? The answer is no because sensitivity is only one measure of receiver performance. The most significant difference between receivers is in their overall signal-to-noise ratios. However, the WWV/WWVH receiver described here has sufficient sensitivity to achieve its dedicated function.

This receiver economizes in the quality of its filters. Most factory-made communications receivers contain expensive precision crystal intermediate frequency (IF) filters which greatly improve the signal-to-noise ratio by screening out most of the noise in the radio-frequency spectrum. Moreover, those communications receivers also have superior intermodulation distortion (IMD) and dynamic range not required for WWV/WWVH reception.

WWV/WWVH transmissions

The WWV transmitter is located in Fort Collins, Colorado, and its signal can be identified by male voice announcements.

FIG. 1—SCHEMATIC OF THE WWV RECEIVER. A short antenna from three to six feet long is sufficient.

WWVH's transmitter is located in Kauai, Hawaii, and its signal can be identified by female voice announcements. Both stations broadcast on exactly the same frequencies, but they do not interfere with each other because their bands are so narrow they sound like a single station when both are received with equal signal strength.

Stations WWV and WWVH operate on a carrier frequency of 2.5 MHz. Station WWV broadcasts with 2.5 kilowatts (kW) of power, while WWVH broadcasts with 5 kW of power. Other frequency-power relationships are 5, 10, and 15 MHz at 10 kW and 20 and 25 MHz at 2.5 kW. The receiver described in this article was designed to receive 10-MHz signals because the author has found that they provide the most reliable reception.

Carrier frequency and all other time-related data is derived from cesium-controlled oscillators that are accurate to within ±1 part in 10^{11}. Daily deviations are less than one part in 10^{12} from day-to-day. Phenomena such as Doppler and diurnal shifts can degrade the accuracy at the receiver, but long-term accuracy of one part in 10^9 can easily be obtained.

There are many different time zones around the world, so it would be impractical to broadcast time for each time zone. To simplify matters, WWV/WWVH transmit time data in *Coordinated Universal Time* (UTC), also known as Greenwich Mean Time (GMT), World Time and Zulu Time.

What is UTC? It is the time in England, uncorrected for daylight savings time, and it is always stated in a 24-hour format. It is called GMT because the zero or Greenwich meridian passes through England, west of London. Table 1 provides information that will permit you to determine the local time-of-day from the UTC announced by WWV and WWVH.

Refer to the sidebar for more technical details on the WWV and WWVH transmission formats. More information on the services of WWV and WWVH can be obtained by writing Frequency-Time Broadcast Services Section, Time and Frequency Division, National Institute of Standards and Technology, Boulder, CO 80302.

WWV and WWVH each have different one minute increments of time, as shown. Minute zero, and all even numbered minutes of WWV begin with a 45-second interval containing either a special announcement or a 500-Hz tone. This is followed by 7.5 seconds of silence except for the one-second *tick*.

The last 7.5 seconds contains the voice UTC time announcement. Minute 1, and all odd numbered minutes, have 45 seconds of a 600-Hz tone followed by the 7.5 seconds of silence except for tick and the 7.5-second UTC time announcement.

WWVH broadcasts with a similar format except even and odd minutes are reversed, and the silent and UTC time announcement intervals are reversed. This prevents interference if both stations are received simultaneously (this occurs on the West Coast of the U.S.). The 45-second interval of each minute might contain variations.

MPF102 JFET, provides input impedance matching and some gain. A double-tuned input filter, consisting of T1, T2, and C4, provides adequate selectivity to attenuate the image frequency of 9.09 MHz.

A Philips NE602N mixer (IC1) contains a double-balanced mixer and oscillator which supplies approximately 14 dB of conversion gain. The oscillator section is crystal controlled to provide stability and eliminate the need for tuning. The output of the NE602N is coupled to a 455-kHz ceramic IF filter (FIL1) with about a 4-kHz bandwidth. The filter's 1500-ohm input and output impedance is matched by resistors R5 and R7. The output impedance of IC1 is 1500 ohms which, with R5, equals about 1500 ohms.

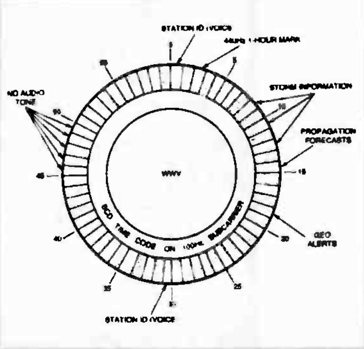
A Motorola MC1350P IF amplifier (IC2) provides about 60 dB of gain with about 80 dB of automatic gain control (AGC) control range. The output is coupled through 455-kHz IF transformer T3. The output impedance of IC2 at 455 kHz is about 200 kilohms. Transformer T3 has a turns ratio of 6:1, and it provides an impedance transformation of 36:1.

Resistor R13 terminates the secondary of T3 with 5600 ohms, to provide the proper primary matching impedance. Other turns ratios can be used for T3 provided that R13 is also changed to maintain the proper impedance match. The input impedance of IC4 is high and it does not significantly affect the impedance match.

The GEC Plessey ZN414Z, an amplifier detector, is packaged in a typical plastic transistor case, but it is actually a ten-transistor IC which provides about 70 dB of gain, detection and some AGC response. It is designed to be powered from a 1.5-volt DC power supply with a 500-ohm load. This is emulated by resistors R15 and R17 whose equivalent circuit is 1.5-volts DC flowing through 500 ohms. The DC level at the output of IC4 is about 1.1-volts DC with no signal, and 0.9-volt DC with a strong signal.

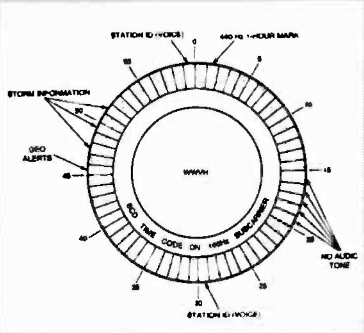
The output signal is amplified, inverted, and filtered by IC3. Capacitor C14 removes any audio from the signal before it is applied to the gain control input

WWV hour signals



The figure shows how the WWV hour is divided. The beginning of each hour is identified by a 0.8-second,1500-Hz tone. The beginning of each minute is identified by a 0.8 second,1200-Hz tone. The 29th and 59th second pulse of each minute is omitted.

WWVH hour signals



The figure illustrates how the WWVH hour is divided. The beginning of each hour is identified by a 0.8-second, 1500-Hz tone. The beginning of each minute is identified by a 0.8-second, 1200-Hz tone. The 29th and 59th second pulse of each minute is omitted.

WWV and WWVH broadcasts are approximate mirror images of each other. This prevents the two stations from creating interference mutual interference during voice announcements.

pin 5 of the Motorola MC1350P IF amplifier (IC2). When the voltage at the output of IC4 exceeds the 1-volt DC reference level set by R10 and R11, the gain of IC2 starts to roll off. As a result, the AGC response of IC2 and IC3 tries to maintain the signal level so that the DC level at the output of IC4 is 1-volt DC.

The gain of the Motorola MC34119P audio amplifier (IC5) is set by the ratio of R20 to R19, which equals 47 (about 16 dB). This audio amplifier was selected because it is a bridge amplifier and does not require a large coupling capacitor to drive the speaker.

The overall maximum gain of the receiver is about 144 dB. This is the sum of a −10 dB in the input filter, +14 dB from IC1, −6 dB in FIL1, +60 dB from IC2, +70 dB from IC3, and +16 dB from IC4. Ordinarily a gain of 144 dB is too much. Normal operation can be expected to be with about a 120 dB maximum gain, which is typical of a high-quality communications receiver. However, the gain is usually less than that, as set by the volume-control potentiometer R18 and AGC loop.

Building the receiver

You can build the receiver on a single-sided PC board that you make yourself from the foil pattern provided here. Alternatively, partial and complete kits containing a finished PC board, as well as complete receivers, are available from the source given in the Parts List.

Figure 6 is a parts-placement diagram. The order of assembling the components to the circuit board and soldering them is not critical. Pay particular attention to the orientation of the semiconductors, that is the location of pin 1. Mount the volume control on the PC board. Keep in mind that it cannot be adjusted after it is installed in the case.

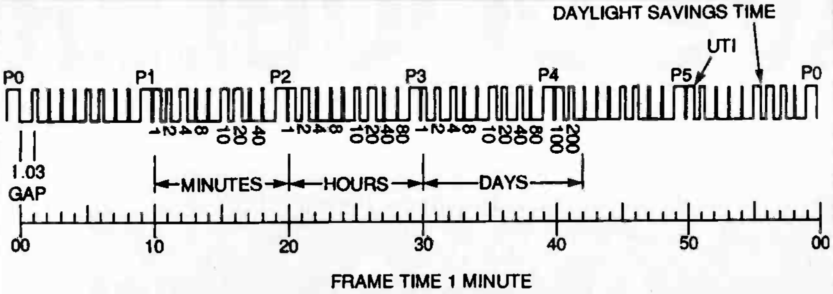
The author designed the circuit assuming that the receiver would be turned on only for brief periods to obtain the correct time, and that convenient access to the volume control would not be necessary. However, if you want an external volume control, one can be mounted on the case and wired directly to the pads intended for the PCB-mounted control.

After all the electronic components are inserted and soldered to the circuit board, wire the speaker, battery clip, power switch, and antenna. Install the completed circuit board in the case as shown in Fig. 7. Install a 9-volt battery.

Circuit alignment

To align the circuit, adjust transformers T1, T2, and T3 for peak AGC voltage at pin 6 of IC3. The desired tuning is broad for receiving a strong signal. Attach an antenna that is as short as practical to pick up an extremely weak signal for the alignment procedure. Even with those precautions, the tuning range of the IF transformers will appear to be quite broad.

Dividing Up Time For Broadcast



The figure illustrates the pulse format for the BCD time code (100-Hz subcarrier). During the passage of a minute, both stations broadcast the time of year on a pulse-width modulated 100-Hz subcarrier. Three different pulse widths are used:

1. P0-P5—position identifiers—0.8 seconds (80 cycles)
2. Logic 1—data bit—0.5 seconds (50 cycles)
3. Logic 0—data bit— 0.2 seconds (20 cycles)

In addition there is a 1.03 second (103 cycles) "hole" in the code for synchronization at the beginning of each minute signal. The minute is divided into six parts of 10 seconds duration. Each part consists of nine data bits and a position identifier pulse. The following listing is the contents of the various sections.

1.—Synchronization "hole" and eight logic zeros.

2.—Four data bits encoding the unit minutes in binary-coded decimal (BCD), a logic 0, three data bits encoding the tens of minutes in BCD and another logic 0.

3.—Four data bits encoding the unit hours in BCD, a logic 0, and two data bits encoding the tens of hours in BCD and two logic 0's.

4.—Four data bits encoding the unit days in BCD, a logic 0, and four data bits encoding the tens of days in BCD.

5.—Two data bits encoding the hundreds of days in BCD and seven logic 0's.

6.—One data bit if UT1 correction should be applied, four logic 0's, a data bit which is logic 1 if daylight saving time and three data bits with the UT1 correction in tenths of a second. The UT1 correction accounts for the Earth's rotation which varies slightly over time.

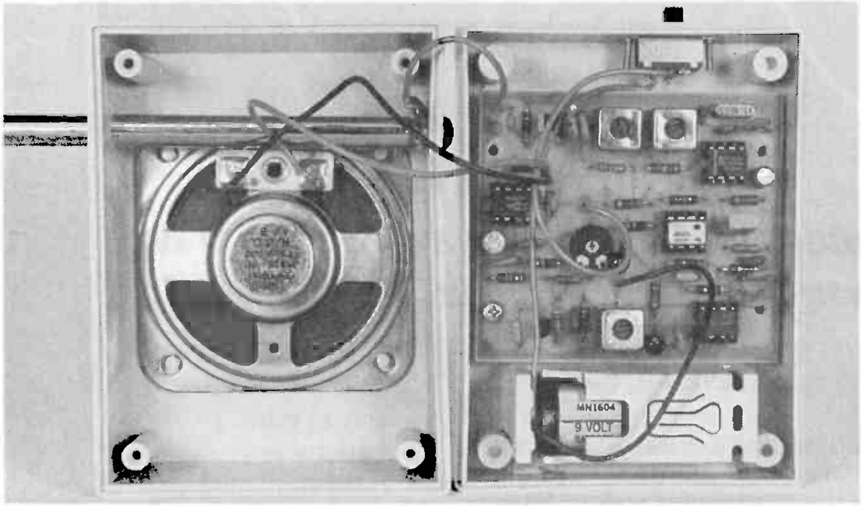


FIG. 3—THE FINAL ASSEMBLY consists of wiring the speaker, battery clip, power switch, and antenna. The author's prototype is shown here.

As an alternative to "on-air tuning," set up a 10-megahertz signal source. It will make the task of circuit alignment easier by providing a constant, local, easy to control signal. The author set a frequency counter at 10-megahertz and its internal oscillator provided sufficient ambient signal leakage to act as an excellent signal source for alignment.

The most difficult step is the alignment of the double-tuned input filter, T1/T2. To overcome that obstacle, all of the transformers that are supplied with the kit from the source listed in the Parts List are pre-aligned. Only slight adjustments are then necessary for the transformers after assembly.

Antenna considerations

The author lives near Seattle, Washington—about 1000 miles from Fort Collins, Colorado. Moreover, there are several mountain ranges between Seattle and Fort Collins. The quality of reception is usually excellent during the day with an antenna consisting of a 3- to 6-foot length of wire. When the signal is particularly strong, no antenna is needed.

The prototype receiver shown in the photographs has a 30-inch telescopic rod antenna that works quite well, but this a convenience feature rather than a requirement. There are two pads on the board for the connecting the antenna: one is connected to the antenna and the other is the ground connection. While a single wire on the antenna terminal usually works well, reception can generally be improved with a simple dipole antenna formed by a second wire connected to ground. Ω

It keeps more than memories alive.

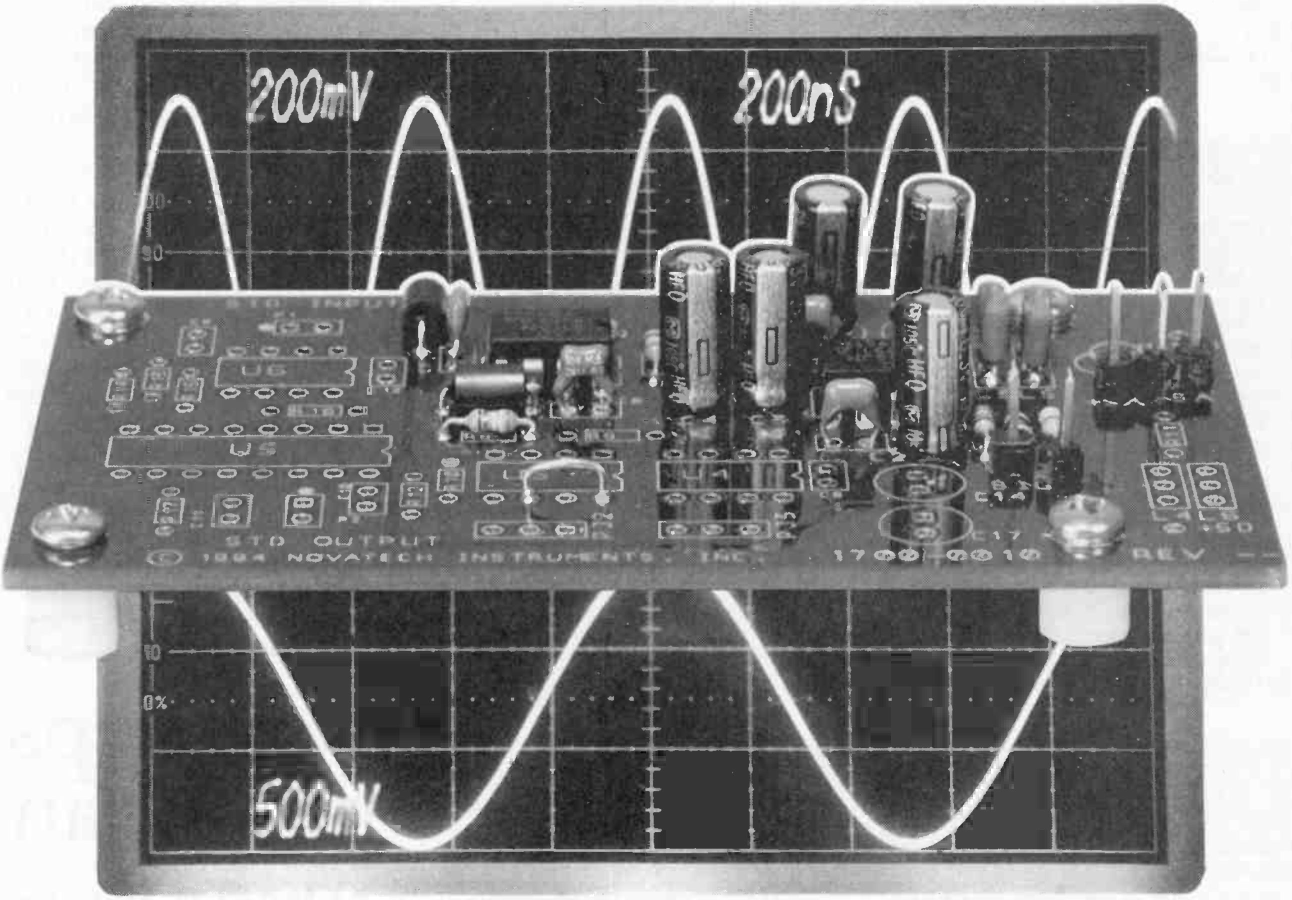
SINEWAVE DOUBLER



Double the frequency of any sinewave from 10 Hz to more than 50 MHz.

STEVEN D. SWIFT

HOW OFTEN HAVE YOU WISHED THAT your signal generator would generate a higher frequency? The small module described in this article doubles the frequency of any sinewave input, providing outputs from 10 hertz up to and beyond 50 megahertz. It measures less than 2 × 3.5-inches, and consumes about one-third of a watt. It can be permanently installed in almost any signal generator or used as an outboard module.

Theory of operation

A schematic of the frequency doubler module is shown in Fig. 1. The core of the module is IC1, an Analog Devices AD834 wideband four-quadrant multiplier. This IC provides wideband analog multiplication of two input signals, regardless of their polarity. In this circuit both X and Y inputs are tied together to provide a squaring function.

The operation of IC1 is best understood with the aid of simple mathematics. If the input is assumed to be a normalized (amplitude of 1) sinewave of frequency f, then the input can be written as:

$$\text{Input} = \sin(2\pi f)$$

where

$\pi = 3.14159\ldots$

f = frequency

t = time

The AD834 performs the following function:

$$XY = \sin(2\pi f) \times \sin(2\pi f)$$
$$= (\sin(2\pi f))^2$$

A fundamental trigonometric identity gives:

$$(\sin(2\pi f))^2 = (1 - \cos(2(2\pi f)))/2$$
$$= (1 - \cos(2\pi 2f))/2$$

The last term shows a DC offset as well as a cosine term with twice the frequency as the input. This performs the frequen-

cy doubling function. The cosine term exhibits a 90° phase shift from the original input, but phase is of no concern in this circuit. Note, however, that the amplitude is cut in half.

Since the AD834 provides differential current-mode outputs, load resistors R4 and R5, gain resistors R6 and R7, and IC2 are added to convert the signal to an amplified and buffered single-ended output. The AD811 wideband current-mode feedback amplifier (IC2) is configured as a differential amplifier. Capacitors C3 and C4 remove the DC offset from the output. Resistor R8 provides a nominal 50-ohm output impedance, and R1 and R2 attenuate the input signal and provide a low-impedance source to IC1.

Inductors L1, L2, L3, and L5 and capacitors C5, C6, C7, C13, and C15 perform high-frequency filtering and decoupling. Resistors R3 and R18 and capacitors C1, C2, and C16 provide decoupling and biasing for IC1.

The circuit requires a +5-volt supply at about 30 milliamperes and −5 volts at about 40 milliamperes. Higher voltages, up to ±9 volts, can be used if the bypass capacitor voltage ratings are increased. Higher voltages provide higher bandwidths with higher power dissipation.

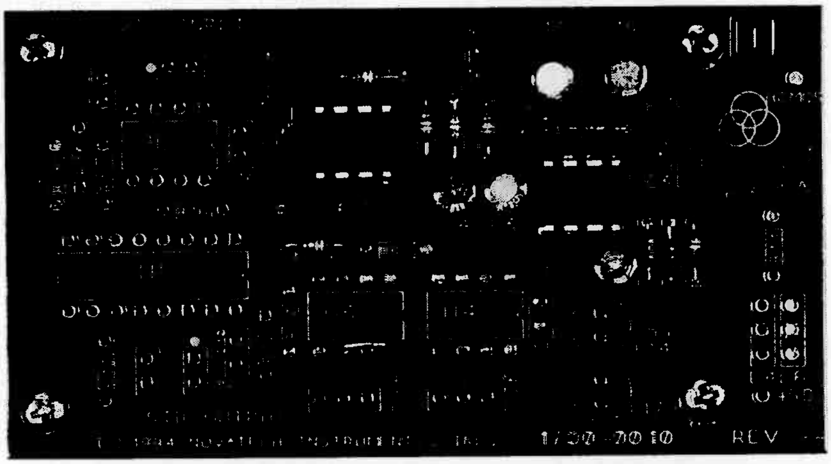

FIG. 3—THE COMPLETED BOARD. The locations for extra components are for other board applications.

Construction

Because IC1 and IC2 are high-frequency components, you must be extremely careful to prevent high-frequency oscillations if you build the circuit on a breadboard. It is preferable to use a PC board. A foil pattern is provided here. Keep all wires short and place the bypass capacitors as close to IC1 and IC2 as possible. A solid ground plane on the component side of the PC board is recommended, and IC sockets are discouraged. If you must use sockets, use machined-pin, open-frame sockets only.

As can be seen from the parts-placement diagram, the board has locations for extra components not related to the doubling function discussed in this article. The additional features were included to allow the board to be used with other Novatech synthesizers.

The parts-placement diagram is shown in Fig. 2. Install all the components as shown, taking care to observe polarity on diodes and capacitors. Square pads indicate pin 1 of all ICs and the positive leads of all polarized capacitors.

All resistors specified for this circuit (except R18) are ⅛-watt, 1% metal-film types. Their small size and tight tolerance improves high-frequency performance and circuit matching. If resistors other than metal-film are substituted, the performance of the frequency doubler

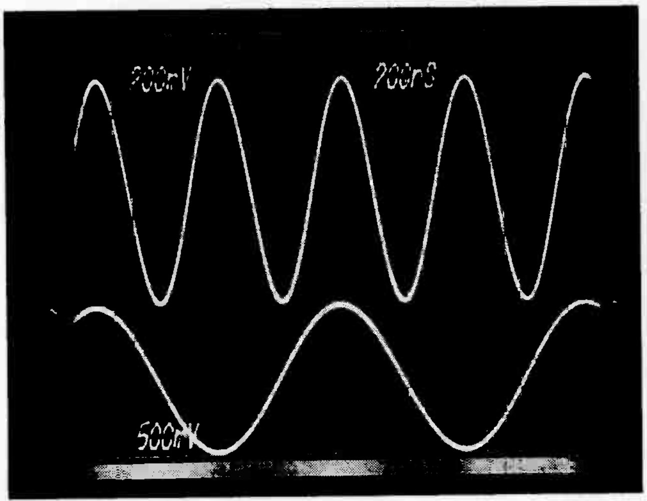

FIG. 4—INPUT AND OUTPUT. The top trace is the output of the doubler with a 1-megahertz, 1.5-volt peak-peak input signal, and the bottom trace is the input signal.

will be degraded. In particular, its distortion will increase, and its bandwidth will decrease.

As mentioned before, C3 and C4 provide DC blocking. The values specified allow operation down to about 10 hertz. If you intend to use this circuit exclusively above 5 kilohertz, better high-frequency performance can be obtained by substituting 0.1 μF ceramic capacitors. The extra capacitors are included with the kit for this purpose. Figure 3 shows the board.

Verify that all components are installed properly and that there are no solder bridges. Apply power to the board as indicated in Fig. 2 (plus and minus 5 volts DC, both ± 0.25 volt). Also connect a function generator set to approximately 1 volt RMS to the signal input as shown. Connect an oscilloscope or frequency counter to the output pin (the center pin of J2).

Observe that the output is double the frequency of the input signal as the input is varied. The typical 3 dB point of the doubler is greater than 30 megahertz at the output. You can adjust the input to vary the output, but with an input above about 1.5 volts RMS, the output might be clipped.

The top trace in Fig. 4 is the output of the doubler with a 1-megahertz, 1.5-volt peak-to-peak input signal, shown at 200 millivolts per division. The bottom trace is the input signal at 500 millivolts per division. Figure 5 shows the frequency spectrum of the output signal in Fig. 4. The fundamental frequency is about 40 dB down from the doubled frequency, the second harmonic is more than 65 dB down, and the third is about 60 dB down. This fundamental frequency feedthrough increases to about −20 dB below the carrier as the output is increased to 50 megahertz. Ω

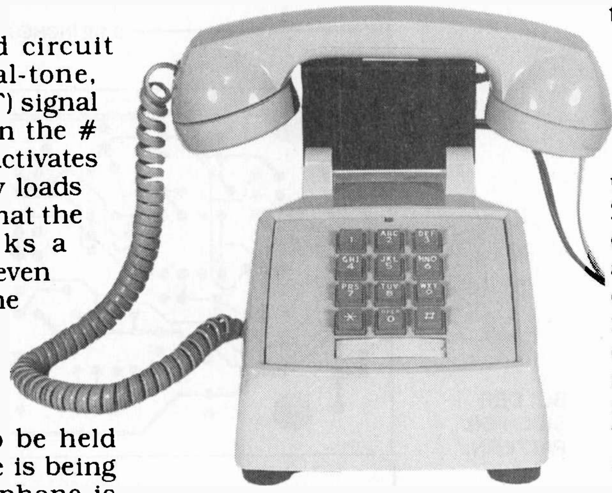
PUT THAT PHONE ON HOLD!

Build a telephone hold circuit that works from any phone in your home—even cordless!

FRANK MONTEGARI



IF YOU HAVE TOUCH-TONE TELEphone service, you can now put a call on hold from any phone in your house by plugging this simple device into any telephone jack. The universal hold circuit works with any phone that has a keypad with a # key. To put a call on hold, press the # key and hang the phone up. A timer extends the #-key function while you hang up phones that have a keypad built into the handset.

The universal hold circuit first detects the dual-tone, multifrequency (DTMF) signal that is generated when the # key is pressed. It then activates a circuit that partially loads the telephone line so that the central office thinks a phone is still off-hook even after it is hung up. The hold circuit remains active for five seconds after the # key is released, so the key does not have to be held down while the phone is being hung up. When any phone is again picked up, the hold function is canceled.

How it works

Figure 1 shows the schematic diagram of the universal hold circuit. The telephone line is connected to the hold components through bridge rectifier BR1 so that the input is not polarity sensitive. The positive side of the line is always connected to Zener diode D2, and the negative side of the line is always connected to IC2. The telephone line also connects to tone-decoder IC4 through C4 and T1. Power is supplied to the circuit by a 12-volt DC power adapter and by IC5, a 78L05 5-volt regulator, and is filtered by C2 and C3.

Optoisolator IC1 contains a silicon-controlled rectifier (SCR) that latches on after it's turned on by current flowing through an optically coupled LED within the IC. The SCR continues to conduct even after the LED current is removed, providing that enough anode current is available to sustain it. When the SCR anode voltage is removed and conduction stops, it will not resume until the SCR is again triggered by the internal LED.

When all phones on the line are on-hook, the voltage across the telephone line is about 48 volts. When a phone is taken off-hook, it places a load on the line and a current of about 20 milliamps flows through the phone, which causes the line voltage to drop to about 3 to 8 volts, depending on the telephone. Current also flows through circuits at the central office, indicating that a phone has been picked up.

A call is put on hold when all phones are hung up and the SCR in IC1 is triggered on by circuits driving its LED. When the SCR conducts, current flows through BR1, D2, LED1, IC1, IC2 and back through BR1, placing a load on the line that keeps the central-office circuits active. A 15-volt drop across D2, a 2-volt drop across D1, a 1.5-volt drop across the LED in IC2, and about a 1.5-volt drop across the diodes in BR1 result in the normal 48-volt line voltage being clamped to about 20 volts. That allows line current to flow, but at a higher voltage than normal. The LED lights to indicate that a call is on hold. When a phone is picked up and the line voltage drops to 8 volts or less, there is no longer enough voltage to keep current flowing through D2, D1 IC1, IC2, and BR1, and the hold function is canceled.

The telephone line also connects through capacitor C4 and transformer T1 to capacitor C8, which couples the DTMF signal to the input of IC4, a Motorola MC145436 DTMF decoder used to detect the #-key tone. Zener diode D6 clamps IC4's input voltage to 9.1 volts to prevent damage from transients. The decoder has four outputs that produce a hexadecimal code corresponding to the tones it receives when a key is pressed (see Table 1). Notice that only when the # key is pressed will pins 13 and 14 both go high (logic "1"). That is convenient, as the circuit has to monitor only two outputs of IC4 to decode the # key.

Decoding the outputs of IC4 pins 13 and 14 is done by a logical AND circuit consisting of two diodes, D4 and D5, whose cathodes must both be high for their anodes to be pulled high by R5. That discharges C1 through R4 into the positive

supply. When the # key is released, pins 13 and 14 go low again and a negative pulse is produced by C1 and R4 at the trigger input (pin 2) of 555 timer IC3. That starts IC3's timing cycle where pin 3 goes high for about five seconds. That drives current through R3 into the LED within IC1, latching the internal SCR. The five-second output from IC3 keeps current flowing long enough to hang up the phone. The 5-second duration is controlled by R7 and C7 and may be altered by changing the value of R7.

Optoisolator IC2 has a transistor output. After the # key is pressed and the phone is hung up, telephone line current flowing through the LED in IC2 turns its transistor on, which resets timer IC3.

The reset function removes current from the LED in IC1 and allows a hold to be canceled immediately after initiating it without having to wait for the five-second cycle to complete. The transistor within IC2 also performs a power-on reset by having its base coupled through C5 to the positive supply. When

power is turned off, C5 discharges through D3.

Construction

Since this is a low-frequency circuit, parts layout and wiring are not at all critical, parts tolerances are not critical, and equivalent types may be substituted.

The prototype was built on a small PC board for which we've provided a foil pattern. Point-to-point wiring will work just as well, however.

If the printed-circuit board is used, use Fig. 2 as a guide to install the parts. It's always best to use IC sockets for all ICs, although they aren't absolutely necessary.

When installing LED1, leave its leads long and bend them in an S shape so its position can be adjusted later on to fit through a hole in the top of the case. After all parts are installed, plug the ICs into their sockets. Keep in mind that IC4 is a CMOS device that is sensitive to ESD or electrostatic discharge. Figure 3 shows the completed PC board.

The author installed the board in a 2- × 3- × 1-inch plastic case (see Parts List), in which the board fits perfectly and is held securely without any hardware. You are free to use any case you like, but the installation details are up to you if you decide to go that route.

Place a nylon tie around the power leads and the telephone wire to act as strain reliefs, or tie knots in them to serve the same purpose. Cut and file slots in the edge of the case to pass the wires through and drill a hole in the top of the case directly above where the LED will be once the board is installed. Figure 4 shows how the board fits into

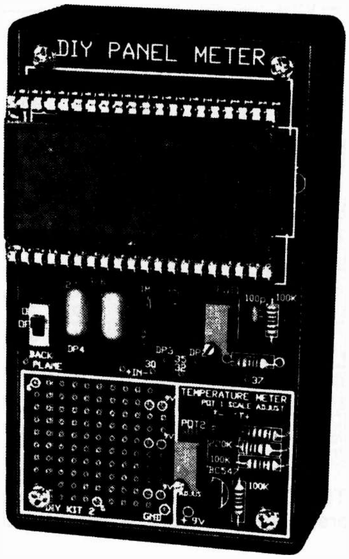
SOLID STATE THERMOMETER

Build an accurate, 3½-digit, handheld thermometer from a kit or from scratch.

MARC SPIWAK



THE LIQUID-CRYSTAL DISplay (LCD) and the single-chip analog-to-digital converter (ADC) have made possible an almost endless list of battery-powered, handheld test instruments. The most prominent of these are the digital multimeter (DMM) and the digital panel meter (DPM), but others include digital capacitance meters, thermometers, timers, sound-level meters, and light meters.

The single chip ADC eliminated a slew of discrete components and increased circuit reliability, while the LCD presents large characters that are easily seen in daylight. But of more importance in battery-powered instruments, both of these components are miserly in power consumption. This is especially important for battery conservation.

Within recent years the prices of single-chip ADC ICs and large-character LCDs have fallen, and they are now readily available as low-cost, off-the-shelf items from electronics stores and distributors.

The digital thermometer described here can be made from an available kit or the parts can be obtained from most electronics distributors. By building the thermometer, the builder will gain experience in working with advanced ICs and display modules, and at the same time gain insight into circuitry common to many different instruments.

The digital thermometer can make accurate, reliable, and repeatable temperature measurements in the laboratory or in the field over a wide range of temperatures. It will save money over the price of a factory-built instrument and, as a bonus, it provides circuit board space for adding extra components for experiments.

The basic digital thermometer circuit displays temperature in degrees Celsius to a an accuracy of a tenth of a degree on its 3½-digit LCD in half-inch high characters. The PC board can be purchased as part of the kit or made with the foil pattern included here. The electronic components are visible on the top surface of the instrument case, as shown in the illustration of the meter.

How does it work?

Figure 1 is a schematic for the digital thermometer. The key semiconductor device in the circuit is IC1, an ICL7106CPL single-chip analog-to-digital converter from Harris Semiconductor. It is a 3½-digit ADC with a built-in LCD display driver, BCD to seven-segment decoders, clock and voltage reference. The ADC is packaged in a 40-pin plastic DIP. In the digital thermometer described in this article, IC1 will be set to display 200 millivolts full scale (199.9), plus or minus.

The temperature sensor for this digital thermometer is an NPN transistor modified to act like a silicon diode. The base of transistor Q1 is short-circuited to the collector, so it functions as a diode. However, it has a response curve that is more linear over a wider temperature range than a diode.

Transistor Q1 provides a variable input voltage to IC1. The voltage drop across the effective diode, typically about 0.7 volt, depends on the temperature of the diode's junction and the current flowing through it. The voltage drop is nearly linear, and will typically vary by 2.2 millivolts per degree Celsius.

A silicon diode has a negative temperature coefficient. Thus, in this application, as the temperature rises, voltage falls, and as the temperature falls the voltage rises. For example, if the ambient temperature rises by 2° Celsius, the voltage drop across the diode will decrease by about 4.4 millivolts. This linear voltage drop is measured to determine temperature.

The kit for the digital thermometer includes two transistors (Q1 and Q2) identified as BC-547s (but marked C547B). Pin identification is shown in Fig. 1. However, more readily available, industry-standard 2N2222 transistors can be substituted, although they have different pinout arrangements. Refer to the instructions given later if you want to make this substitution.

(ZERO control) and R10 (SCALE control) can be set to zero the meter and make scale adjustments in the input voltage to IC1. A display of 00.0 must correspond to zero degrees Celsius and the display temperature must increment in degrees Celsius. The multiturn potentiometers permit precise settings.

Because IC1 can also indicate the polarity of the input voltage, the digital thermometer is theoretically capable of displaying temperature measurements from −200 to +200 degrees Celsius. However, the transistor used as a temperature sensor and its leads could be damaged by those temperature extremes.

The digital thermometer is effectively a solid-state voltmeter that could be adapted for making other measurements such as voltage, current, power, light level, and sound intensity, and more. If the output of the sensor for the variable you want to measure can be scaled between 0 and 200 millivolts, the circuit presented here can display that variable in appropriate standard units with little or no circuit modification.

The PC board for this project contains a small space where additional components can be

located and powered to perform experiments and make other kinds of measurements.

Figure 2 is the parts placement diagram for this meter. The circuit could be wired point-to-point, but that would call for a lot of wiring, especially in the display section. Consequently, the use of a PC board is recommended.

Insert all leaded components and sockets, and solder them in place on the solder side of the board. Insert resistor R1 and trimmer potentiometer R10 in individual machined pin sockets (two for R1 and three for R10) if you might want to replace those components with others having different values for different applications.

However, if you have no intention of experimenting with the finished meter, solder all resistors directly to the board. If you intend to substitute 2N2222 transistors, insert Q2 with its flat side opposite that shown in Fig. 2. More instructions on the substitution of 2N2222s will be given later.

Notice that analog-to-digital converter, IC1, is located under the LCD display, DISP1. When IC1 is installed, mount the LCD directly above it while orienting it to the opposite polarity (the notches are on opposite sides of the board). First install a socket for IC1. Then cut two 40-pin sockets apart along their long axes to provide four single in-line (SIP) sockets. Insert one SIP socket within another to form two double-height SIP sockets. These will leave enough "headroom" for positioning IC1.

Solder the two double-deck SIP sockets to the board for DISP1, as shown in Fig. 2, and then install IC1. Then insert DISP1 in the double-height SIP sockets. This arrangement makes it easy to remove DISP1 by leaving the upper socket strips attached to the LCD and prying them away from the two lower socket strips that are soldered to the board. CAUTION: Do not attempt to remove the LCD from the upper sockets because the display pins can bend, and the glass body can break.

Cut a scrap of tinned lead wire to form jumper "J," insert and solder it. If you buy the digital thermometer kit, a case is included. The PC board fits securely in the top of the case to form a cover. Therefore, the inside the case provides enough space for the 9-volt battery. Solder the battery clip leads to the solder side of the board at the points shown in Fig. 2.

Refer to Fig. 3 and short-circuit QI's base lead to its collector lead near the body of the transistor by bending them together and soldering them. Slip short lengths of heat shrinkable tubing over each input end of a two-conductor cable. Solder the two shorted transistor leads to the positive sensor input wire and

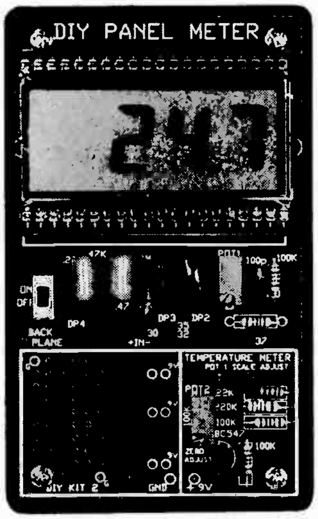

FIG. 4—THE TEMPERATURE-SENSING transistor can be located on the PC board, but leads must be attached for calibration.

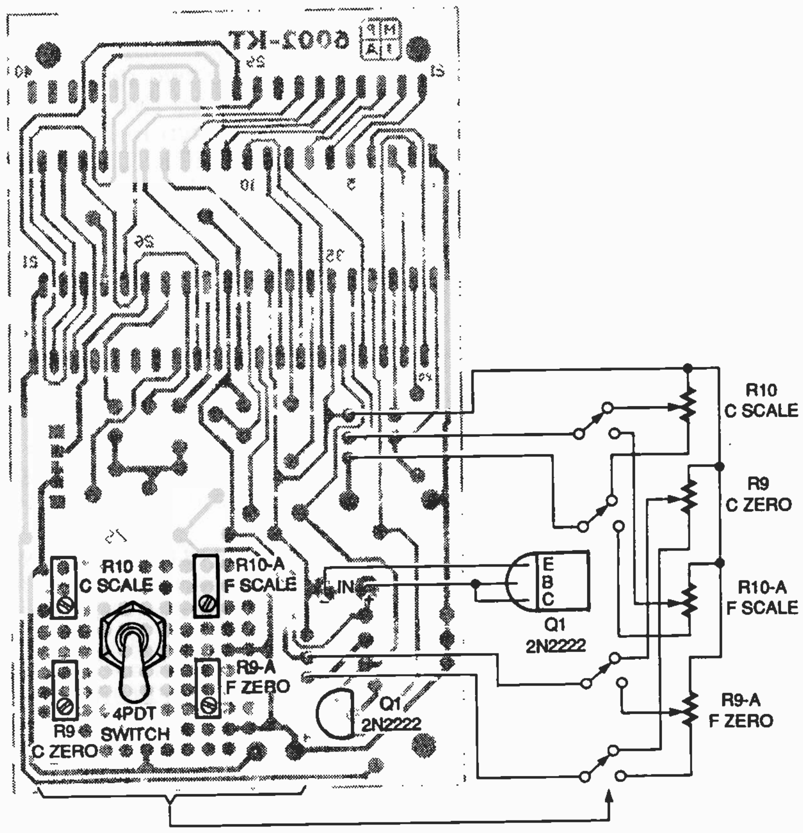

FIG. 5—THE CIRCUIT CAN BE MODIFIED as shown here to display part of the Fahrenheit scale in addition to the Celsius scale. Alternative 2N2222 transistors are installed as shown.

the emitter lead to the negative input wire.

Slip a short length of heat-shrinkable tubing on both leads and pull it over the end of the transistor to form an outer protective jacket, as shown in Fig. 3. Heat the tubing so that it forms a tight shrink fit around both the end of the transistor and the cable.

Standard insulated hookup wire leads are suitable for the temperature probe up to about 6 inches long. However, if the probe is to be mounted on leads longer than 6 inches, use thin shielded cable.

The temperature probe can also be mounted on the PC board directly with leads soldered to the "+" and "−" probe inputs. This arrangement will, however, make thermometer calibration more difficult. If you elect this option, temporarily attach the probe to the board with leads for calibration and mount it permanently to the board afterward. Figure 4 shows the completed digital thermometer.

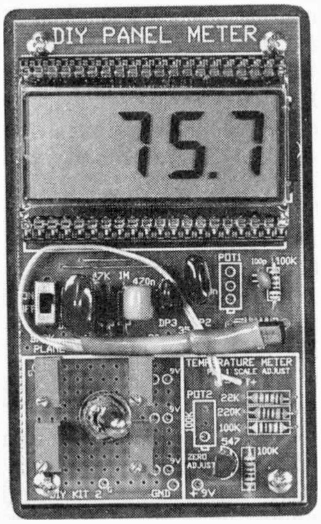

FIG. 6—MODIFIED THERMOMETER can display the full Celsius range and Fahrenheit from about 60° to about 80°.

Modifying the meter

As mentioned earlier, a small area on the PC board is set aside to accommodate components for experiments. We added two more potentiometers and a 4PDT switch to the circuit so the digital thermometer could be calibrated in Fahrenheit as well as Celsius degrees. Those modifications are shown in Fig. 5. The same figure also gives details for installing the alternative 2N2222 transistors, should you decide to substitute them.

Our tests showed that the meter's response is not perfectly linear for the Fahrenheit scale, and it is impossible to calibrate it at the boiling point of water because 212° cannot be displayed on the 3½-digit display. However, the response was linear enough for the display to give an accurate Fahrenheit reading from about 60 to 80°, the range in which most temperature readings are likely to be taken.

Calibrating the meter

Carefully inspect the circuit board for soldering errors and correct them before proceeding. If the board passes visual inspection, connect a 9-volt battery to it and switch on power. The display will either indicate a "1" or some other reading. If the display shows a "1," adjust potentiometers R9 and R10 to obtain a reading other than a "1."

Fill a container with ice cubes and add a small amount of water. Turn on the digital thermometer and submerge its temperature probe in the ice water, holding it in close contact with an ice cube. Wait until the display stabilizes and then adjust ZERO control potentiometer R9 until the display reads 00.0.

Boil water in a kettle and carefully hold the probe over the kettle spout in the steam with tongs to prevent accidentally scalding yourself. When the display reading stabilizes, adjust SCALE control potentiometer R10 until the display reads 100. If you have access to a digital multimeter with a temperature probe that is known to be calibrated, compare readings and adjust trimmers R9 and R10 more precisely.

If you added the Fahrenheit potentiometers, as shown in Fig. 5, calibrate the Fahrenheit scale next, bearing in mind the limitations discussed earlier. It is recommended that the tem-

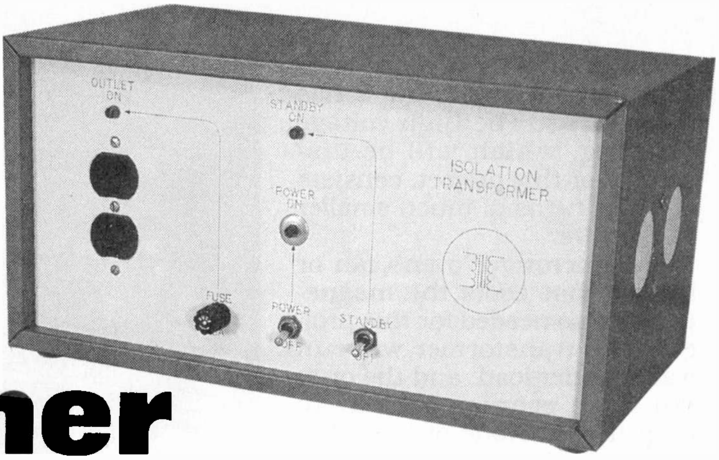
Home-brew Isolation Transformer



Buils this inexpensive transformer to protect yourself—and your test equipment— while you service and repair electronic appliances.

DOYLE WHISENANT

EVERYONE WHO REGULARLY SERvices television sets really should have an isolation transformer. One side of the chassis of most line-powered TV receivers and tube-type radios is connected directly to the AC line. Therefore, servicing this electronic equipment can be very dangerous because the chassis can be "hot." An isolation transformer isolates the chassis of the equipment being serviced from the AC line. This article explains how to build an isolation transformer for a fraction of the price of a commercial product. It will even supply more current than most commercial units.

The heart of this project is the transformer. The author obtained the two transformers required from two discarded microwave ovens. Buying a new transformer for this project will not save you much money over buying a commercial isolation transformer because the transformer required can cost more than $150. For example, B&K Precision sells an isolation transformer for $189.00. Although electronics distributor Mouser Electronics sells one for $63.50, it will supply only 2.17 amperes, or about 250 watts. Even this modest price is almost three times what our complete project will cost!

Operation

Figure 1 is the schematic for the isolation transformer. Fuse-protected AC line power is first applied to power switch S1. When S1 is closed, neon power indicator NE1 lights up, and power is applied to a cooling fan and to standby switch S2. This arrangement allows transformer power to be turned off, while permitting the fan to continue cooling the transformer.

Neon standby indicator NE2 is wired across switch S2 so that it lights when S2 is open. When S2 is closed, power is applied to the primary side of 1:1 isolation transformer T1. The secondary side of T1 supplies isolated AC power to receptacle SO1. Neon indicator NE3 lights when power is applied to the receptacle SO1.

The isolation transformer will supply 1000 watts for short periods of time, and 500 watts or less continuously. However, it will run too hot if 500 watts is exceeded for more than about half an hour.

The transformer for this project was made from the windings of two microwave-oven transformers. Microwave ovens have heavy-duty transformers (see Fig. 2) that consist of three windings: a 120-volt AC input coil, a 2000- to 3000-volt AC output coil, and a 3- to 5-volt AC coil that serves as the filament winding for the oven's magnetron. The magnetron is the vacuum tube that produces the microwave energy for the oven.

The filament winding is easily identified; it consists of three to five single turns of 12- or 13-gauge enamel-covered wire. This winding is usually wound directly over the 120-volt AC winding which is wound from

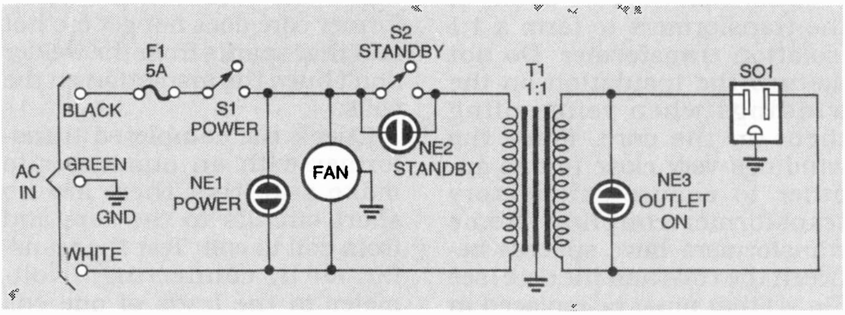


FIG. 1—ISOLATION TRANSFORMER SCHEMATIC. Switch S2 allows power to the transformer to be turned off while the fan continues to cool the transformer.

approximately the same size wire as the filament, but it has more turns. The high-voltage winding, which will be discarded for this project, consists of many turns of much smaller gauge wire.

The microwave oven's fan or blower that cools the magnetron is also needed for this project. The transformer will run warm under load, and the oven fan is an economical way to keep it cool. None of the other parts (see the Parts List), while commonly available, will be found in a microwave oven.

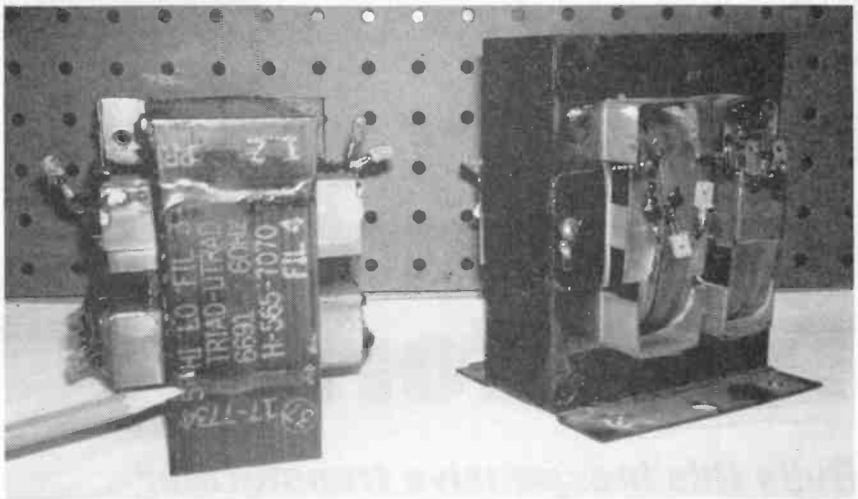

FIG. 2—THE TRANSFORMER for this project was made from two discarded microwave-oven transformers.

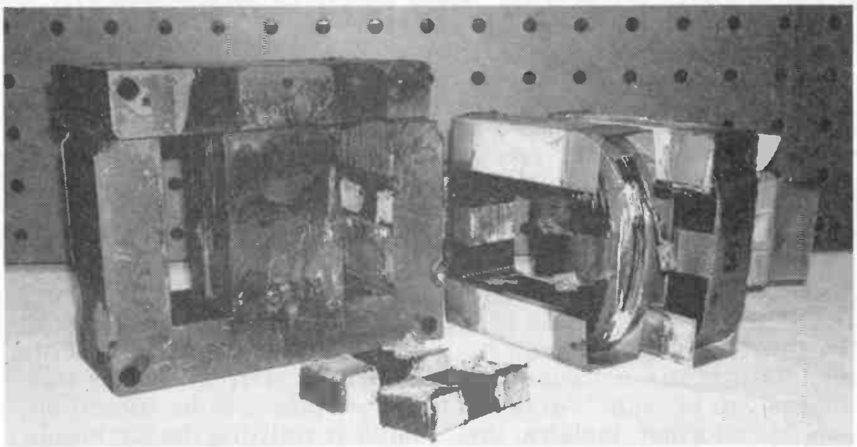

FIG. 3—DISASSEMBLED TRANSFORMER. Remove the windings from the transformer core, being careful not to disturb the insulation on the windings. Discard the high-voltage windings.

Modifying the transformer

Locate two surplus or discarded microwave ovens that are identical, or as similar as possible. As stated earlier, the transformers from two ovens are needed to build the isolation transformer. These transformers usually remain in good working condition. As an alternative, two surplus transformers might be easier for you to obtain than two scrap microwave ovens.

The pencil in Fig. 2 points to one of the welds that must be removed from the microwave-oven transformer. With a handheld grinder, very carefully grind away the welds on both sides of the transformer and separate the top core from the base. Figure 3 shows a transformer that has been disassembled. Remove the windings from the core, being careful not to disturb the insulation on the windings. Discard the high-voltage windings.

The 120-volt AC input coils from the two transformers will be used to make the isolation transformer. Place both 120-volt coils back on the core of one of the transformers to form a 1:1 isolation transformer. Do not disturb the insulation on the windings when reinstalling them on the core. Place the windings very close to one another to ensure satisfactory transformer coupling. Some transformers have spacers between the coils and the core (see Fig. 4) that must be replaced in the correct locations.

Once the windings are correctly positioned back on the core, reinstall the base of the transformer. To do this, weld the base back onto the transformer. If you have access to an electric welder and know how to use it, do this yourself. Otherwise, take the transformer to a welding shop and let a skilled welder do the job for you. Regardless of who does the welding, make sure that the transformer core does not get too hot and that sparks from the welder don't burn the insulation on the coils.

Check the completed transformer with an ohmmeter to make sure that there are no short circuits to the core and from coil to coil. Test the transformer by connecting a voltmeter to the leads of one coil designated as the output coil. Connect the leads from the other coil to an AC line cord through a 5-ampere fuse. Insulate all exposed connections.

Power up the transformer just long enough to get a reading on the voltmeter. Record the output reading, disconnect the AC power, and reverse the input and output coil connections. Repeat the procedure and check the output voltage again. Determine which output coil voltage measures closest to 120-volts AC; it will be the output side. The prototype transformer had a lower voltage reading in one direction than in the other.

Construction

This project requires a sturdy metal case that measures approximately 14- × 7- × 9-inches to hold both the fan and the transformer, and still have room for all connections.

This project consists of only a few parts, so point-to-point wiring can be used throughout. Figure 5 shows the inside of the prototype unit. Test fit the fan and the transformer before drilling any holes in the case. The fan should be mounted so that its air stream is directed at the transformer. Once the correct positions are determined for the fan and transformer, mark the locations and drill the mounting holes, but don't mount anything yet.

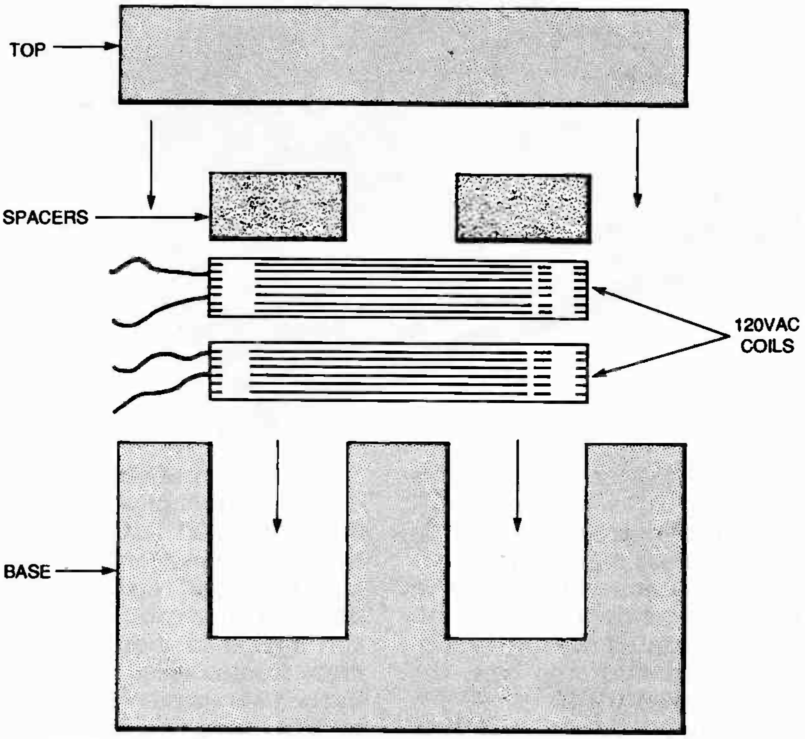

FIG. 4—SOME TRANSFORMERS have spacers between their coils and the core.

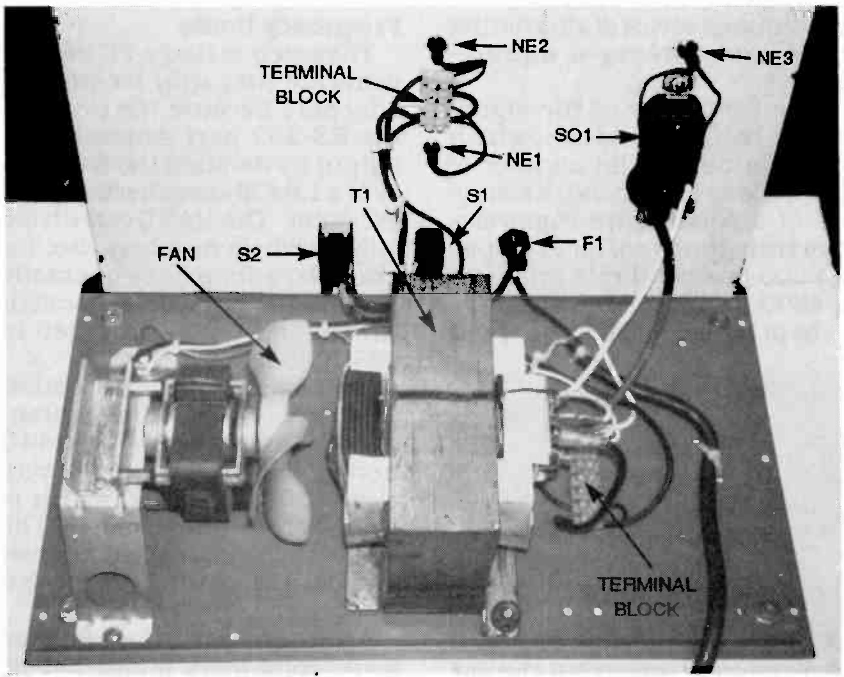

FIG. 5—POINT-TO-POINT WIRING is used throughout this project.

If you purchase the case specified in the Parts List, you will find that many of the necessary holes are already punched out. Otherwise, prepare the enclosure by drilling a hole and mounting the line cord to the back of the enclosure. Prepare the front of the enclosure by drilling holes to mount the neon indicators, NE1, NE2, and NE3. Then drill holes for switches S1 and S2. The prototype unit has two large holes punched in each end to allow the fan to draw in cool air and exhaust hot air. Place a screen over those holes to prevent debris from being drawn inside the unit. Prepare an opening for the duplex receptacle on the front panel with a nibbling tool.

Once all the metal working on the enclosure is complete, it can be painted. Next label the enclosure; the labels can be protected with clear spray enamel.

When the enclosure is completely dry, the transformer and fan can be mounted. Start with the transformer, mounting it to the base of the enclosure with rubber washers to reduce vibration. Mount the fan in the direction so that the cooling air flow will be blowing over the transformer. Next install the fuse holder, the line cord, the three neon indicators, switches S1 and S2, and the duplex receptacle SO1.

The isolation transformer can produce several amperes of current, so use 14- to 16-gauge wire for all connections to and from the transformer. However, smaller gauge wire can be used for connecting the fan and neon indicators.

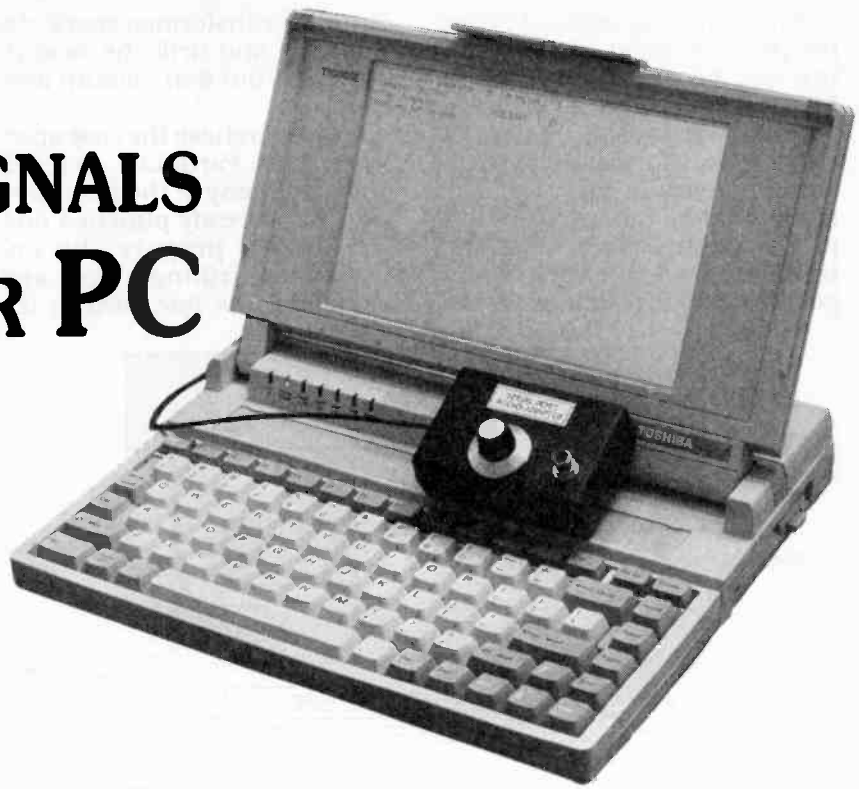
PRECISION AUDIO SIGNALS FROM YOUR PC



Build this computer-controlled audio generator—for under ten bucks.

MICHAEL A. COVINGTON

DO YOU NEED A PRECISION SQUARE-wave generator for audio testing? If so, look no further than your computer's serial port, a handful of passive components, and a very simple 30-line BASIC program.

That combination can deliver signals with frequencies as high as 4800 hertz, and with crystal-controlled accuracy of 0.1% or better. The software was developed on an IBM-compatible PC, but it should run on just about any computer.

How it works

The trick is U, the ASCII character "U," that is. The hexadecimal value of "U" is 55, which in binary is 01010101 (with eight data bits and no parity, or seven data bits and even parity).

The RS-232 protocol specifies that the bits of an ASCII character are transmitted from least to most significant, preceded by a start bit (always 0) and followed by a stop bit (always 1). So, after adding the requisite start and stop bits, the result is 1010101010.

Now suppose a string of U's is generated at the serial port at some steady rate. The result is a continuous series of alternating ones and zeroes—a squarewave.

The frequency of the signal will be half the baud rate, which by definition is the number of transitions per second. Each cycle of a squarewave comprises two transitions so, for example, a 9600-bps baud rate produces a 4800-hertz squarewave.

In practical terms, just about any computer should be able to deliver frequencies of 55, 150, 300, 600, 1200, 2400, and 4800 hertz, corresponding to the standard baud rates from 110 to 9600. In addition, the signal can appear at many other discrete frequencies, limited only by the CPU speed of the computer. But there is a catch to this scheme.

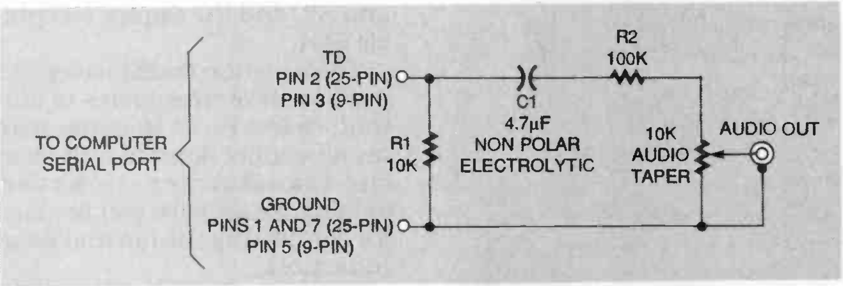


FIG. 1—COMPLETE CIRCUIT of the precision audio generator requires just a handful of passive components.

Frequency limits

The catch is that a PC cannot generate just *any* frequency. Why not? Because the UART in the RS-232 port generates its output by dividing the frequency of a 1.8432-megahertz crystal oscillator. The UART can divide only by whole numbers. So, for example, a frequency of exactly 1000 hertz can't be generated; the nearest you can get is 993.1035 hertz.

If you want to tune a guitar, you can't quite produce a standard concert-pitch "A" (440 hertz), but you can get a very clsoe 439.6947 hertz, which is off by only 1/80 of a semitone. The software will display the nearest standard value to any requested frequency.

Another limitation is that some computers might not be able to deliver high frequencies, because they can't output U's fast enough. In that case, squarewave bursts, with silence in between, is generated. If you could hear that, it might sound like buzzing, flapping, or clicking superimposed on the high-pitched tone. The best way to detect this kind of problem is with an oscilloscope or frequency counter.

Even if the computer is fast, there can be breaks in the squarewave. That can happen if the computer is doing task-switching (e.g., under Windows), or if it is heavily loaded with terminate and stay resident programs (TSRs). But under DOS, the author had good results up to 4800 hertz with an old Toshiba laptop.

Hardware and software

There's not much to the circuit, which is shown in Fig. 1. The output of a serial port is nominally 24 volts peak-to-peak, which is much too high a voltage to feed to the input of an audio amplifier. The circuit attenuates the signal to a more useful level, a variable 2-volts peak-to-peak. The circuit also protects the computer from static electricity and voltage surges. Capacitor C1, a non-polarized unit, blocks DC because the serial port, when idling, outputs approximately −12 volts.

The attenuator consists of only four components, so it does not need a PC board. The circuit was built in a small plastic case by mounting the resistors and capacitors directly to the potentiometer and output jack, as shown in Fig. 2. Figure 3 shows the assembled unit.

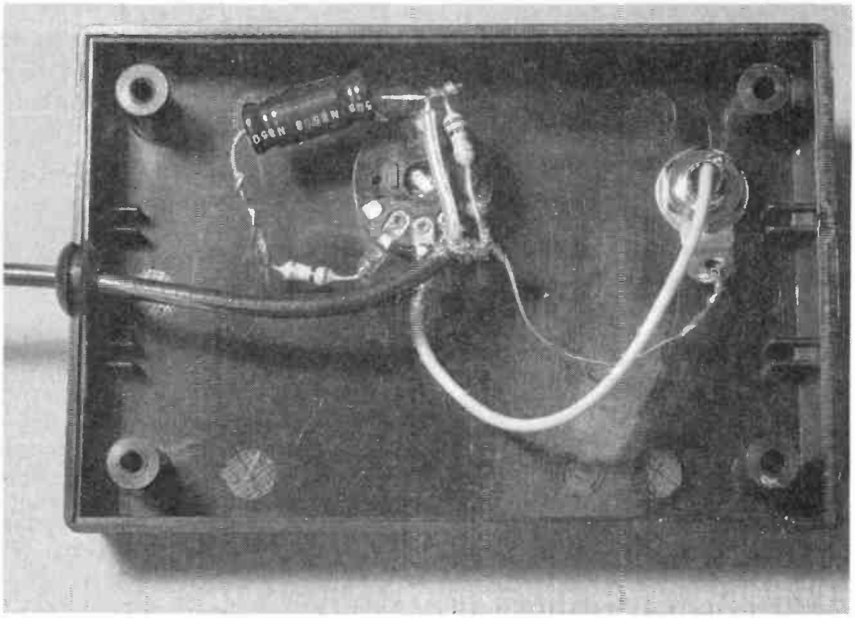

FIG. 2—MOUNT ALL COMPONENTS directly on the potentiometer, as shown here. This eliminates the need for any kind of circuit board.

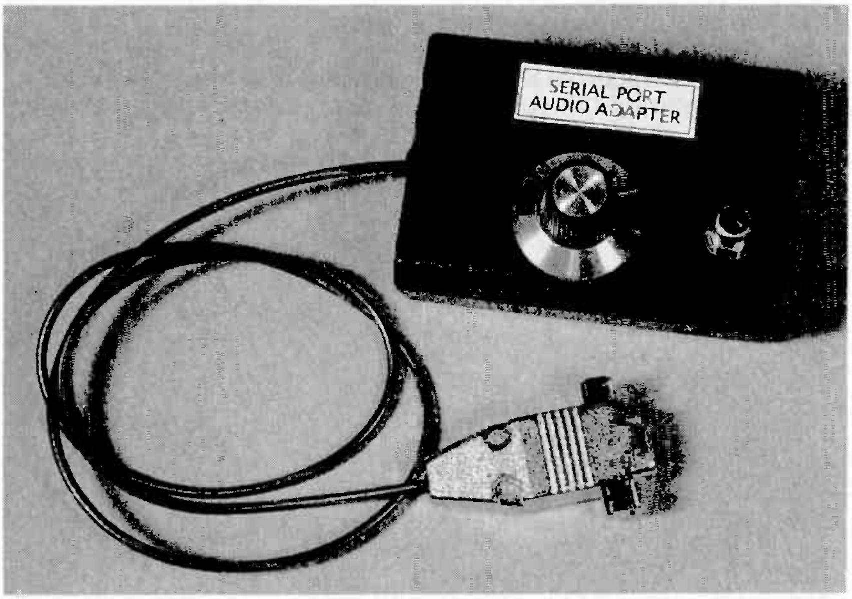

FIG. 3—THE ASSEMBLED UNIT is compact and attractive. An even smaller case than the one shown here could also be used.

If you want the circuit to deliver signals for testing, just run an appropriate cable from J1 to your equipment. For audio output, say for tuning musical instruments or playing audible tones, the circuit can drive a speaker directly, as shown in Fig. 4.

A word of caution before discussing applications: RS-232 ports are supposed to be tolerant of static charges, short circuits, and extraneous voltages, but be aware that some ports are not. Use extra care if your port is part of a multifunction card that also includes a disk controller.

Many of these cards include both the serial port and the disk controller in a single, fragile VLSI device. If part of the circuit fails, you're likely to lose the whole thing—including access to your disk drives. Generally speaking, when experimenting with accessories connected to a serial port, it's safer to use a card with discrete RS-232 transmitter and receiver ICs.

As for the software, Listing 1

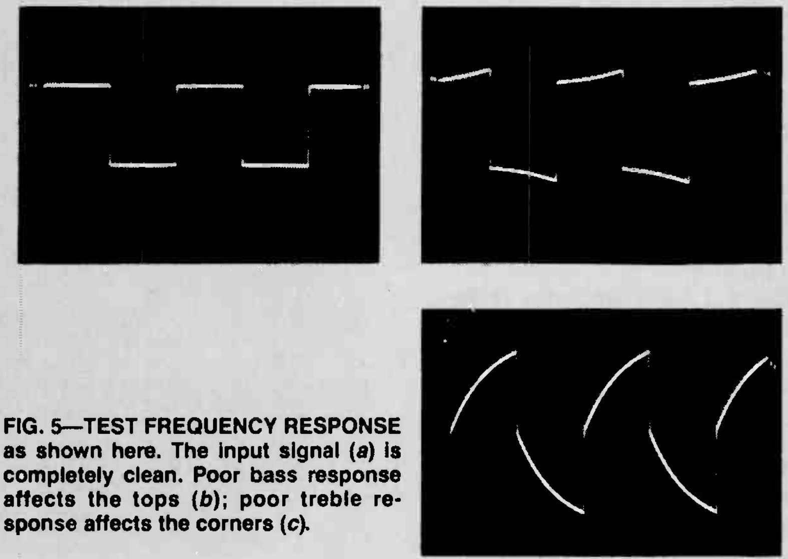

FIG. 5—TEST FREQUENCY RESPONSE as shown here. The input signal (*a*) is completely clean. Poor bass response affects the tops (*b*); poor treble response affects the corners (*c*).

shows the complete program. After setting up several constants, the program requests an output frequency, displays the nearest attainable value, and then starts pumping U's from the serial port. That continues until the user presses a key and then it stops.

The constants defined in lines 120 and 130 specify values for the PC's standard COM1 serial port. To use a different port, make the appropriate modifications. Also note line 190, which specifies the dividend in the frequency calculation. To run the program on another computer, that value might have to be adjusted.

Putting it to use

A precision squarewave generator has many applications. For example, you can use it to test the frequency response of an amplifier, as shown in Fig. 5. The input signal to the amplifier appears in Fig. 5-*a*; note the signal's sharp corners and flat tops. If the amplifier circuit has poor bass response, the tops of the waveform won't be flat (Fig. 5-*b*); if the treble is weak, the corners of the waveform won't be square (Fig. 5-*c*).

In general, a clean looking squarewave at the output of an amplifier indicates a good frequency response over a 100-to-1 range. For example, an amplifier that cleanly reproduces a 1-kilohertz squarewave should provide good performance from 100 hertz to 10 kilohertz. Be aware, however, that a squarewave test won't detect clipping in the amplifier.

I have already mentioned tuning musical instruments. Another application is testing wow and flutter in tape recorders. Generate a constant frequency and record it; then play it back while comparing it to the same frequency coming directly from the computer. You can do the comparison by ear, but it's better to use an oscilloscope, with one squarewave going to the external sync input and the other to the vertical input. Then look closely to see how much the waveform jiggles from side to side. Ω

INTRODUCTION

Building projects is fun! Exactly where the most fun is can be debated. Is it in the actual assembly of the gadget? What about designing added features or molding it to particular needs? How about watching friends and family "pop eyes" as you exhibit its operation? Who knows? Never examine a pleasure, just enjoy it! With that admonition, inspect the plans of the seventeen projects presented in this Project Anthology while you heat up your soldering iron.

The experience level required of the project builder is minimal. Of course you require some level of project building experience but every effort has been made to keep the level of difficulty down. In some projects the illustrations go beyond the schematic diagram to include mechanical layout information. Although your electronic theory understanding may be scant, you will require higher levels should you indulge in designing additional functions and features into the projects presented herein. Here are general notes about the parts used in projects.

Resistors. Fixed-valued resistors are rated at either 1/4-watt or 1/2-watt, within 5 percent of their designated value. One-half watt is the preferred rating for resistors because of their physical size and ease of handling on circuit boards. Hobbyists with construction experience should select the wattage size that they deem suitable for the project. Resistors that are specified with wattage ratings may be substituted for other resistors of higher wattage rating. For example: you could replace a 1-watt resistor with a 3-watt resistor provided that the replacement is not of wire-wound construction. Wire-wound resistors have a measure of inductance in them and they may upset the operation of the circuit, especially high-frequency audio and radio circuits. The physical size of the resistor increases significantly with its power rating so common sense directs that you do not use outlandish substitutions. Only composition resistors are used in the following projects. Do not substitute different ohmic values unless the text discusses the possibility, or you are thoroughly qualified to make ohmic value changes by adequate academic knowledge and/or experience.

Capacitors. The voltage ratings of capacitors in the projects should be equal to or above that specified in the Parts List. Electrolytic capacitors should be reasonably close to the specified value in microFarads. The working-voltage-DC (WVDC) rating must never be less than specified, and as a rule never more than twice the specified rating. Two capacitors connected in parallel add their values. Two capacitors, say .10-µF and .25-µF in rating, when connected in parallel will be equal to a single capacitor rated at .35 µF. When paralleling capacitors to obtain useable values, be sure that the WVDC ratings of both capacitors are at least equal to the specified value.

Semiconductors. Solid-state parts such as transistors, integrated circuit chips, diodes, LEDs, etc., cause the most problems for new project builders. It is recommended that they obtain catalogs from retail and mail-order outlets. Radio Shack is an excellent retail source—there's one in every town in North America that has more than two traffic lights, or so it seems. There are a host of parts advertisers who offer free 800 telephone numbers so you can do your shopping at home. Some readers resort to substitution listings for what appears to be hard-to-get parts. This could be risky for beginners because pin connections vary with so-called identical units. If you are calling an 800 telephone number parts outlet, insist upon the exact part. There are enough 800 electronic parts suppliers in North America to call and get the parts you want.

Light-emitting diodes (LEDs) usually have their cathodes identified by the shorter lead which is closest to the flat edge of the circular rim at the base of the part. There are variances, and for bi-color LEDs, this is true for one of the colors only. If you have any doubts, do not hard solder the LED into the circuit at first. Run a power-on test and if the LED does not light, or the wrong color comes up, reverse the leads and try again. The LED should light or the correct color appear. Now you can solder the LED into the circuit. Solderless circuit boards can be used for testing mockups.

Not every construction or parts problem can be forecasted, however, experience is a great teacher and you will learn much by jumping into the construction of a simple project. Experience grows with practice. The fantasies of the Project Anthology are now all yours to enjoy. Have fun!

THE PROJECTS

1 Twinkle Tree

Twinkle Tree is an easy project for beginners to build, and its basic circuit has a number of useful applications. The circuit's visible action appears as a string of ten LEDs (light-emitting diodes) flashing on one at a time in sequence, this being repeated so long as the circuit is powered.

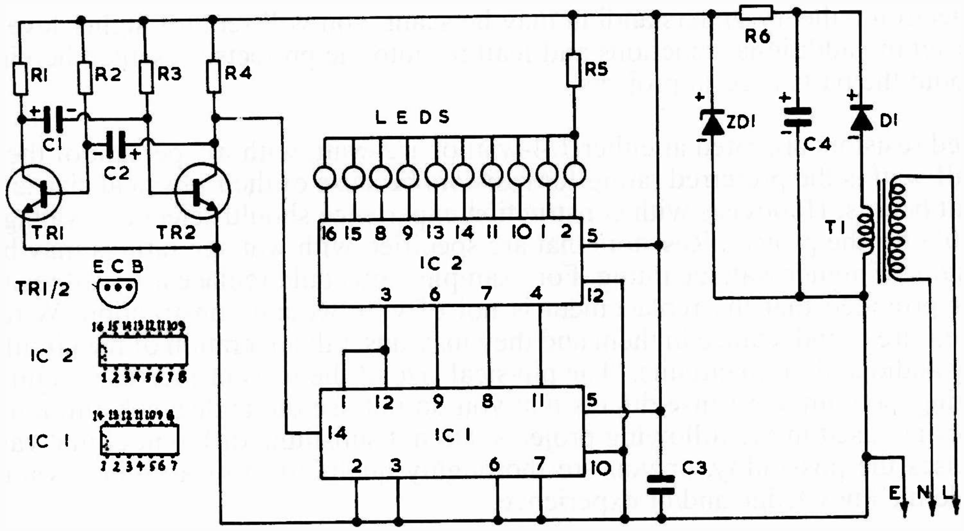

Fig. 1– Circuit diagram for the Twinkle Tree project.

The LEDs can be used on a small table decoration, in the form of a Christmas tree (we call it Twinkle Tree), or around a picture frame; or they may be placed at various points on a hanging decoration, such as a bunch of mistletoe, or can be incorporated in other decorations or models. The LED light display provides an interesting and novel twinkling effect.

The same circuit can be used with the LEDs placed round a small display, so that they flash on in turn with a revolving or racing effect.

How It Works. Figure 1 is the schematic diagram of the circuit for Twinkle Tree which includes a small power supply for operation from AC lines. If the circuit is to be powered from an existing supply, or batteries, omit circuit components ZD1, D1, R6, C4 and T1. The external power supply negative line goes to the "E" line in Fig. 1, and the positive line to the junction of resistors R1 through R5. The voltage supplied should be approximately 5-volts DC. You may want to connect an AC wall-plug power pack rated at 5-volts DC as the power source. Do not use 6-volt DC from dry cells or else the ICs will be damaged. 4.5-volt DC from three 1.5-volt dry cells may be used, however the LEDs will appear to be a bit dimmer.

The multivibrator circuit consists of transistors Tr1 and Tr2 which produces pulses that form

the input to the binary-coded, decimal-decade counter IC1, at pin 14. This IC counts the pulses and provides a binary output at 1-12, 9, 8 and 11 pins. Pin 5 is its positive line, and 10 is its negative line.

With counters having two or more numerals, as shown later, the IC can pass on a pulse to the "tens" section. Here, it is used alone and repeats the same series of outputs over and over so long as the multivibrator pulses are applied to pin 14.

Chip IC2 is a decoder-driver. Its purpose is to receive the various inputs at 3, 6, 7 and 4, and decode them into outputs at 16, 15, 8, 9 and so on, along to 1 and 2. Thus each of these ten points provides a circuit to the appropriate LED in turn. The outputs connected to LEDs are located at the top of IC2 when Fig. 1 is held right-reading.

All the LEDs are returned through the common limiting resistor R5, to operate from the same 5-volt DC line. The effect is, that each LED is illuminated in turn, along the line, and when the last is reached, this is followed by the first, and the sequence is repeated. Check the LED polarity, and mark this with red sleeving material, or other means, if the LEDs have no means of identification (long lead or flat side).

For the Twinkle Tree the ten LEDs are scattered at random, and any LED could be connected to any of the outputs 16 to 2.

Only one LED is on at a time, so current drain is only some 50 mA or so, and this small current load makes battery operation feasible and long lasting.

Transformer T1 (6.3-volt AC secondary) provides about 9-volt peak across C4, and R6 drops this for the 5.1-volt DC Zener diode ZD1. A meter placed across this diode should read about this voltage.

AC line current is drawn from a 3-pin powerplug line cord with a 2A built-in fuse. The green lead ground circuit in the power cord provides safe grounding of the secondary and low-voltage circuit. A double-insulated transformer specified as requiring no grounding may be operated without grounding through the AC power cord's green lead. Nevertheless, always play safe by using a ground circuit whenever using the AC line. Naturally construction and wiring must assure that no AC voltages can reach the transformed secondary output or the low-voltage circuit.

Construction. This is where the fun in electronics begins. Design your own Twinkle Tree. Maybe you would want to add a few fixed (always-on) LEDs or build two circuit boards and have twice as many twinkling lights. It's up to you!

2 One-Second Flasher

When making a long exposure using a camera with the shutter set to "B" or "T", some sort of timer is needed in order to obtain accurate results. Unless very long exposures are required, a simple one-second indicator such as the One-Second Flasher is probably the ideal solution. The unit pulses on a LED (light-emitting diode) indicator at one second intervals. The shutter is opened as the LED flashes, and then closed after the appropriate number of flashes have been counted off. There are almost certainly a great many other uses for a simple timer of this type, and it could be used as a simple enlarger timer for example.

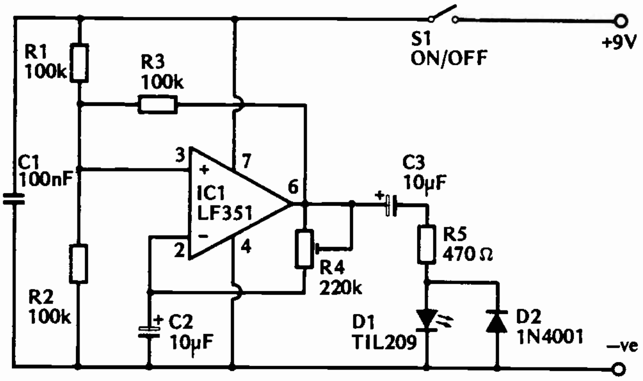

Fig. 2 –Circuit diagram for the One-Second Flasher.

How It Works. The circuit diagram for the One-Second Flasher appears in Fig. 2, and is based on an operational amplifier that is biased by R1, R2 and R3 to act as a form of Schmitt trig-

ger. The output goes to the low state if the inverting input is taken about 2/3V+, and high if it is taken below 1/3V+. The output therefore goes high initially, but C2 soon charges to 2/3V+ via R4, and then the output goes low. Capacitor C2 then discharges to 1/3V+ via R4, sending the output high again, and producing continuous oscillation.

Resistor R4 is adjusted to give an operating frequency of one Hertz. The One-Second Flasher can be calibrated against a watch or clock with a seconds hand by empirical means. The output of IC1 is coupled to the LED indicator, D1, by way of DC blocking capacitor C3 and current limiting resistor R5, and the LED is briefly pulsed on as the output voltage swings positive. Diode D2 ensures that there is both a charge and discharge path for C3 so that the output signal is properly coupled to D1.

The current consumption of the unit is about 2 mA.

As You Like It. Assembly and packaging of the unit is left to the builder. The circuit can be housed in a plastic cassette holder. The LED need not protrude because the case is clear. The circuit uses very little current so that a 9-volt transistor-radio battery can be used. The battery can be disconnected by unsnapping the clip connector or adding a single-pole, single-throw slide switch.

3 5-Volt Power Supply

The series of 7400 TTL integrated circuits are intended to operate from a 5-volt DC supply as are many other modern chips, and integrated circuit voltage regulators for this purpose are available.

The 5-Volt Power Supply shown here will provide voltage-regulated power for digital ICs

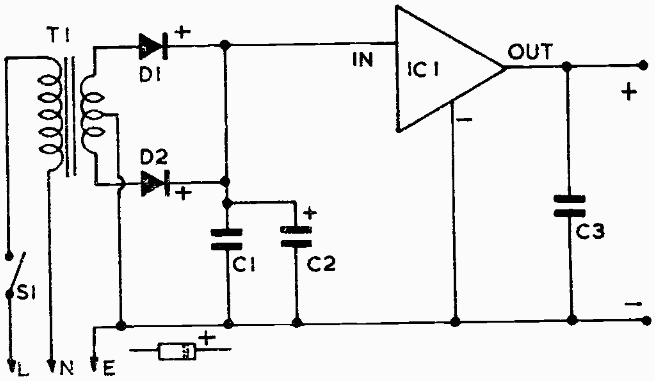

Fig. 3– Circiut diagram for the 5-Volt Power Supply.

needing up to 500 mA. By constructing the 5-Volt Power Supply as a separate unit, any circuit to be operated can be plugged in, and this allows it to provide power for various projects. It may also be used where a 5-volt DC, 500 mA supply is suitable, so it can in some cases be pressed into service where a 4.5-volt or 6-volt battery would otherwise be fitted.

The Circuit. Figure 3 shows the schematic diagram for the circuit. Transformer T1 provides isolation from the AC power line, and has a 9-0-9-volt, 500-mA secondary winding. After rectification, the DC input voltage for IC1 is something over 9-volts. A filament transformer rated at 12-0-12-volts AC may be substituted.

Diode rectifiers D1 and D2 are rated at 50 volts at 1 A: These diodes are readily available. Capacitor C1 helps suppress transients arising from the AC line, and C2 is the main smoothing

(filtering) capacitor. Here, a value of 1500-μF to 3500-μF may be used. Higher capacitances provide better voltage-ripple smoothing.

Chip IC1 is the LM341, a 5-volt, 500-mA positive regulator. Actual maximum current depends to some extent on other factors. Here, heat sinking is to a small metal chassis.

box chassis. This can be a 4 X 6-in. chassis with enough height to clear the top of the transformer, T1. Follow the layout in the diagram when assembling the project to avoid errors.

Safety. The AC line power cord has three leads, green for ground or earth (E), white for neutral (N), and black for live (L) conductors. A thin power cord (#18 gauge) is adequate. Use a 3-pin fused plug, and place a low-rating fuse of 2A or 3A in this.

The cord passes through a rubber grommet, and its conductors are anchored on the 3-way terminal strip. Note that the switch S1 is placed in the live conductor (L) lead. The earth (E) lead (usually green in color) is connected to the chassis. This is also connected to the transformer core, and to the output negative line. If this lead is omitted and the negative return provided by the chassis is to be relied upon, be sure the attaching screws are very tight, and will not become loose.

The grounding is for safety. If a short circuit should arise in T1 or elsewhere, which could carry AC line voltages to the chassis and low-voltage output circuit, the low-rating fuse in the plug will blow.

The unit needs to be enclosed in an aluminum chassis box or case, so that no hot AC leads can be touched.

Safety, with this unit and similar AC line-operated power supplies, depends upon sound construction, correct wiring, fusing and grounding, and shielding of high-voltage points against accidental contact by the user. No high voltage must ever be able to arise on the low-voltage output sockets, or low-voltage wiring as equipment connected to the unit will no longer be safe to touch.

Testing. A DC voltmeter should show approximately 5-volts at the output terminals. Due to tolerances in IC1, and lack of exact accuracy of the meter, the reading might be very slightly above or below 5-volts.

To check for regulation, connect a load taking up to about 500 mA. A 6.3-volt, 0.3 A or 3-watt light bulb is suitable. The reading at the output sockets should remain virtually unchanged.

4 Sound-Switch

The Sound-Switch circuit of Fig. 5 is suitable for use in a sound-activated tape recorder and similar voice-activated applications. Provided a reasonably sensitive crystal microphone is used, the unit will operate from speech of normal volume at a range of several feet. To go beyond that range will invite the rustling of paper, coughs, heel clicks, crowd and traffic noises, air conditioner noise, and many other room and out-of-door noises that will obviate the need of Sound-Switch. A too sensitive sound activated switch would be on most of the time when placed in a noisy environment and a super sensitive microphone used to increase range would be worthless.

How It Works. The circuit uses IC1 as a low-noise preamplifier having a voltage gain of 270 times, and this is followed by a second stage of

amplification which gives a similar voltage gain. The second stage uses Tr1 in the common-emitter mode and this is a conventional arrangement except for the inclusion of C4. This capacitor provides a considerable amount of high-frequency attenuation, and this is necessary in order to prevent instability. Capacitor C5 couples the greatly amplified output of Tr1 to a rectifier and smoothing circuit which gives a positive DC output signal which is roughly proportional to the input signal level. If the input signal is sufficiently strong, the bias voltage at the gate of VMOS device Tr2 will be adequate to bias this transistor into conduction, and the relay which forms its drain load is then activated.

A pair of normally open relay contacts are used to control whatever item of equipment is operated by the unit. Of course, the voltage at the gate of Tr2 soon decays as C6 discharges through R8 if the input signal ceases, and the relay is then switched off. The decay time is roughly one second, which is about the optimum time for most applications. The attack time of the circuit is only a fraction of a second, and the unit responds almost immediately when a sound is initially picked up by the microphone.

Using It. You may want to record your voice giving instructions or reports, such as announcing the disassembly of a complicated component. As you speak, imitate the police and military who use such equipment. Begin each sentence with the word, "Kay." For example, "Kay. Removing the pawl from the gimbals." On playback, all your important words are not clipped and you have an accurate disassembly procedure that can be reversed for assembly purposes.

As the circuit has a fairly high level of gain the component layout must be designed with reasonable care, although the very limited bandwidth of the circuit greatly reduces the risk of instability. The current consumption of the unit is about 3 mA under quiescent conditions, but this increases considerably when the relay is activated. The circuit may be operated from a 9-volt transistor-radio battery, but you may want to use six C cells in series or a wall-plug power pack.

5 LIGHT ALARM

The Light Alarm unit produces a noticeable audio tone when the unit's photocell is subjected to a reasonably high level of light; normal daylight and artificial room lighting are sufficient to operate the circuit. The Light Alarm could be used as a simple burglar deterrent, and it would then be placed in a cabinet or a drawer, and would produce the alarm signal if the cabinet or drawer was opened by a burglar. The sudden noise would hopefully unnerve him or her sufficiently to make them leave the premises immediately. In the case of diet cheaters, the Light Alarm should be refrigerated. It could also be used in a medicine cabinet to sound a warning if a small child should somehow manage to open the cabinet. In this application the on/off switch should be fitted somewhere on the outside of the cabinet (preferably out of sight on top of the cabinet where a small child would be unable to reach it and probably be unaware of its existence) so that you could switch the alarm off before opening the cabinet, and switch on again after it has been closed.

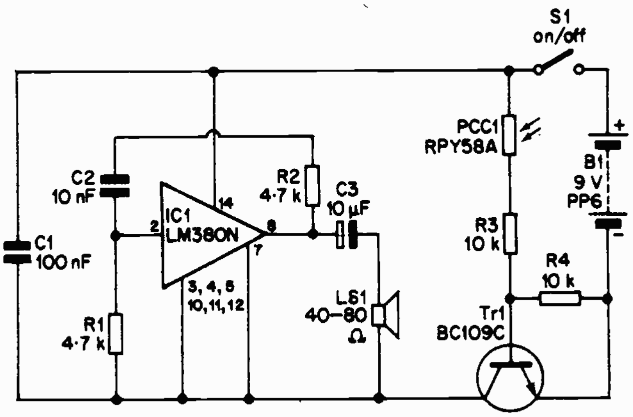

Fig. 6—The circuit diagram of the Light Alarm.

How It Works. The circuit is activated if Tr1 is switched on by a suitable base current and voltage. Refer to Fig. 6. The voltage and current available at the base of Tr1 is dependent on two main factors, the resistance provided by R4, and the setting of control VR1. If VR1 is set at maximum value, photocell PCC1 needs to have a resistance of about 10,000 ohms to bias Tr1 into conduction and activate the audio alarm circuit of which IC1 is a primary part. Fixed resistor R4 has been used across the base-emitter terminals of the switching transistor so that the sensitivity of the circuit is preset. However, R4 can be raised somewhat in value if increased sensitivity is required. Alternatively, it can be replaced with a 100,000-ohm linear potentiometer if a variable in sensitivity is required from time to time.

The audio-alarm generator uses an LM380N (IC1) in a simple audio-oscillator circuit, and drives high-impedance loudspeaker LS1 via coupling capacitor C3. It is a simple matter to get a non-inverting amplifier having a fairly high gain to oscillate, and it is merely necessary to provide AC coupling from the output to the input. Provided the losses through this coupling are less than the voltage gain provided by the amplifier this will give sufficient positive feedback to sustain oscillation.

The values for R1, R2, and C2 shown in the circuit diagram (Fig. 6) give considerably more feedback than is needed to just sustain oscillations and the circuit oscillates strongly producing a squarewave output at a frequency in the region of 1 kHz (1000 Hz).

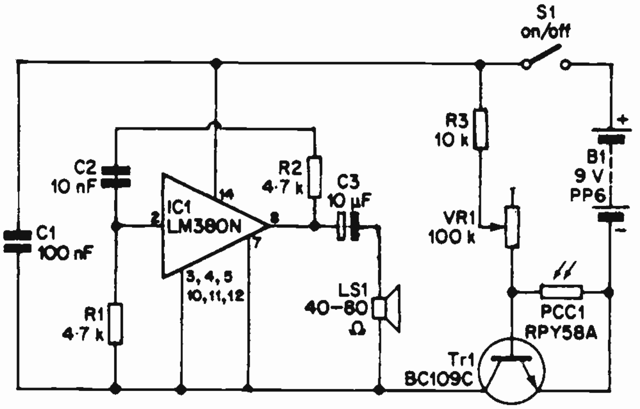

Fig.8–The circuit diagram of the Dark Alarm.

The breadboard component layout for the Light Alarm is shown in Fig. 7.

Incidentally, it is possible to alter the sound tone produced by the circuit; an increase in the value of R1, R2, or C2 (or more than one of these) produces a reduction in pitch, and vice versa.

Dark Alarm. With a minor circuit change (compare Fig. 6 with Fig. 8) the Dark Alarm circuit is similar to the Light Alarm just described, but it operates an audible alarm if the light intensity received by the photocell falls below a certain threshold level, rather than if it exceeds the threshold level. A possible application for the unit is as a headlights-on reminder for the driver of a car. The circuit will operate properly from a

SIG-TRACER

The purpose of a Sig-Tracer is much the same as that of a signal injector. However, a signal tracer is, in a way, used in the opposite manner to a signal injector. Instead of injecting a signal at the output of the equipment under investigation and then working towards the input, a signal tracer is used to first verify that an input signal is present, and further tests are then made at strategic points working stage-by-stage towards the output of the equipment. When the signal can no longer be traced (or is obviously at too low a level, seriously distorted, or in some other way incorrect) the approximate area of the fault has been located. Normal voltage testing and similar checks are then used to precisely locate the fault.

A signal tracer for use on audio equipment simply consists of an audio amplifier driving a loudspeaker or an earphone, so that the traced signal, if present and correct, will give the appropriate audio output from the signal tracer. For RF or IF signal tracing the signal tracer must additionally have a suitable demodulator built-in so that an audio signal is produced from the tracer, provided a suitable input signal is present, of course.

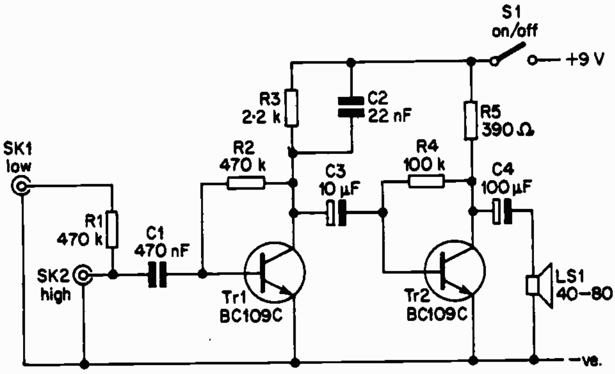

Fig. 9— The circuit diagram for Sig-Tracer.

The Sig-Tracer has good sensitivity so that it can be used for any normal type of audio signal tracing. The circuit provides AM demodulation, and the Sig-Tracer can therefore be used for IF and RF testing on AM radios provided a suitably strong antenna signal is available. The unit has an integral loudspeaker, and although the maximum output power is only a few tens of milliwatts, the volume level obtained is more than adequate for this application. If preferred though, the loudspeaker could be replaced by an earpiece or headphones. Low, medium and high impedance headphones are all suitable for use with the unit.

The Circuit. The circuit diagram for the Sig-Tracer (see Fig. 9) is basically just two common-emitter amplifiers with capacitive coupling. Transistor Tr1 is the input stage, and has C1 to provide DC blocking at the input, R2 as the bias resistor, and R3 as the collector-load resistor. An input signal from jack SK2 direct to the input of the amplifier (Tr1) may well be sufficient to overload the amplifier in many cases, and a second input having lower sensitivity is therefore provided (SK1), and the necessary attenuation (of nearly 40 dB) is provided by R1 and the input impedance of the amplifier. The input impedance of the amplifier at the high-sensitivity input (SK2) is several thousand ohms, but R1 provides a useful boost in input impedance so that the input impedance at SK1 is approaching 500,000 ohms.

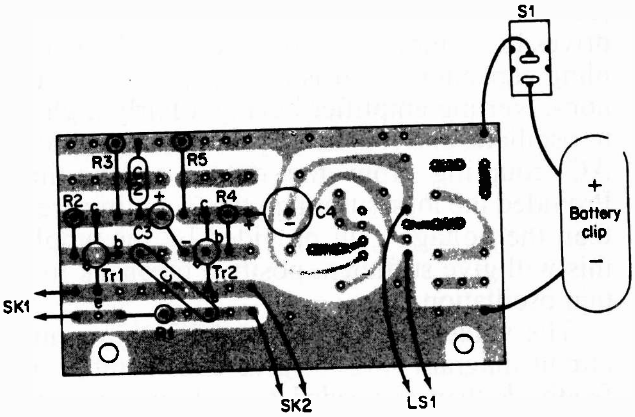

Fig. 10—The components layout for Sig-Tracer.

Capacitor C2 is used to roll-off the high-frequency response of the circuit in order to aid stability. It also gives the circuit a simple AM demodulator action by providing RF filtering. The rectification that is also needed in order to produce AM demodulation is provided by transistor Tr1 which, like any amplifier, does not give perfect linearity. It tends to amplify more during positive input half cycles when the collector current increases than it does on negative input half cycles when the collector current decreases. This form of non-linearity is typical of any normal bipolar transistor, and gives the required rectification. There is no need to have any AF/RF switching since the circuit will properly process either type of signal.

The output from the collector of Tr1 is coupled to the input of Tr2 by C3. Tr2 is used as a straightforward common emitter stage, but it is

run at a fairly high collector current of around 15 mA so that a strong enough output signal to give reasonable volume from a high-impedance loudspeaker can be obtained. C4 couples the output signal to the loudspeaker.

Construction. Before you begin, remember that it is advisable to fit this project into a metal case grounded to the negative terminal of the power supply so that the circuit is screened from stray electrical signals. A suggested component layout on a printed-circuit board for the project is shown in Fig. 10. The project is simple enough to do without a printed-circuit board and may be assembled on a perf-board or some conventional pre-etched, general purpose, circuit board. As the input and output of the unit are in-phase, keep the speaker leads reasonably well separated from the input leads in order to minimize stray feedback and give good stability. It should not be necessary to use shielded leads to connect the board to jacks SK1 and SK2 in order to reduce feedback oscillations, but the external lead which connects to these sockets should be a shielded type.

The current consumption of the Sig-Tracer is about 17 mA, and, a standard 9V transistor-radio battery will not last very long on continuous service. This will not matter in many cases since the unit is likely to be used intermittently during troubleshooting procedures. However, if it is envisaged that the unit will be used quite frequently and for long periods it would be wiser to use a larger battery.

7 CW Filter

Although the IF filtering of shortwave receivers has tended to improve somewhat over recent years, few receivers have a very narrow bandwidth available, and this results in more adjacent-channel interference during CW (Morse code) reception than is really necessary. You have heard this interference: voice, music or heterodyne signals (even excessive static) riding over code. A simple way of obtaining improved results with a receiver that does not have a built-in CW filter is to use an add-on audio filter having a narrow bandwidth. If the receiver has a good filter for SSB reception, using an audio filter plus the SSB filter during CW reception should provide excellent results. We have just the unit for you: our CW Filter.

The CW filter is connected between the headphone or loudspeaker socket or terminal strip of your receiver, and either the headphones or an external loudspeaker. The output of the receiver should have an impedance of 8 ohms or more. As the circuit provides unity gain at pass frequencies and a low impedance output, there should be no problems with a mismatching when the filter is in use.

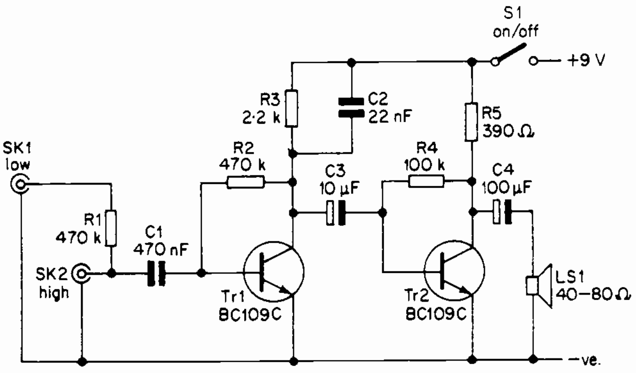

Fig. 11— Circuit diagram for the CW Filter.

The frequency response of the circuit peaks at approximately 800 Hertz, and the -6-dB bandwidth is about 300 Hertz or so. The -0 dB points occur at about 350 Hertz and 2 kHz. This is sufficient to normally give a substantial reduction in adjacent channel interference, but the response is not so narrow and peaky that using the receiver with the filter in circuit becomes difficult, with the wanted signal tending to drift out of the pass-band and become lost.

The Circuit. Resistors R1 and R2 (see Fig.

11) form a simple attenuator which is needed to counteract the gain of the circuitry that follows, and thus give unity voltage gain overall. The rest of the circuit is a conventional operational amplifier bandpass filter having the circuit values chosen for the desired center frequency and a high Q value (to give the required fairly sharp, peaky response).

An ordinary operational amplifier would not give good results in this circuit due to the limited current drive capability of typically just a few milliamps. A few high-current operational amplifiers are available, but even these can usually only provide a few tens of milliamps, and cannot provide a very high output power. This circuit is based on a TDA2006 device which is primarily intended for use as an audio power amplifier having an output power of up to about 10 watts, and the output overload protection circuitry within the device limits the output current to about 3 amps!

Although intended for use as an audio power amplifier, the TDA2006 is a very adaptable device because it can really be regarded as an operational amplifier having a high-power, class B, output stage. The TDA2006 has inverting and non-inverting inputs with a high-input impedance (5 Megohms) at each of these, plus a high open-loop voltage gain over the audio frequency range. Unlike many audio ICs which are basically operational amplifiers, the TDA2006 does not have any internal biasing components, and it can therefore be used, as it is here, in standard operational amplifier circuit configurations.

The lowest recommended supply voltage for the TDA2006 is 12 volts, but it seems to operate well using a 9-volt battery as the power source. The current consumption is around 20 mA or so, and this can rise substantially if the circuit is used at high volume with an 8 ohm load. It is therefore advisable to use a fairly large battery pack or suitable 12-volt DC wall plug power pack. A supply voltage of 12 or 15 volts is perfectly acceptable provided C6 working DC voltage (WVDC) has a suitable high, maximum-voltage rating.

Construction. The component layout and wiring of the CW Filter are illustrated in Fig. 12. Construction of the component panel is very straightforward, and there are no breaks needed in the copper strips. IC1 has pre-formed leads and it is necessary to splay the readouts slightly in order to fit them onto a 0.1-in. matrix. IC1 should not need a heat sink if the circuit is battery powered, but this might be necessary if a 12 or 15 volt high-current battery supply or AC-line power supply is used.

If an operating frequency other than 800 Hertz is desired, the center frequency of the filter can be changed by altering the values of C1 and C2. The operating frequency is inversely proportional to the value of these capacitors, but note that reducing the center frequency also reduces the bandwidth of the filter, and increasing the center frequency gives an increase in bandwidth.

When first using the filter it may appear to give a large reduction in gain, and this is simply due to the fact that at most frequencies the filter does give a substantial amount of attenuation. The CW note from the receiver must be fairly accurately tuned to the center of the filter's response in order to obtain a strong output, and after a little experience with the unit, this tuning will be found to be quite easy.

8 Vol-Expander

Many types of live music, particularly classical music, have a very wide dynamic range. The dynamic range of music is simply the difference between the maximum and minimum sound levels, usually expressed in dBs. This dynamic range can be over 70 dB (although in most cases it is not quite this high).

To record this type of music requires a certain amount of compression being used in one form or another, especially in the case of a cassette recording where the available dynamic range of the recording system (tape and machine) is likely to be limited. Without some form of compression to restrict the dynamic range of the signal either loud passages of music overload the recording or transmission medium, or quiet passages fall into or below the noise level (or a combination of the two).

Music that has undergone even a small amount of carefully applied compression can be rather lacking in musical impact. You hear that kind of flat, background music in elevators and banks. An improvement in the playback can often be obtained by using a certain amount of expansion during playback or reception in order to boost the effective dynamic range of the signal. In order to give the desired effect an expander is required not to affect low-level signals, but produces a small boost in volume at middle dynamic levels, steadily rising to an increase of about 10 or 12 dB at the highest dynamic levels. In this way the lowest volume levels (and the background noise) remain unaltered, but the highest volume levels are substantially boosted. Of course, some noise is also boosted, but this is not noticeable as the wanted signal is strong enough to mask the noise.

Thus the use of a volume expander gives an apparent increase in signal to noise ratio, and can give more impact to music which requires a wide dynamic range. A volume expander cannot be expected to precisely counteract any compression used during the recording process or during transmission, but it can nevertheless produce a substantial subjective improvement when used with many program sources.

This all leads to the Vol-Expander that is our budget version of a practical volume expander hobbyists can build and use with rewarding music enjoyment.

The Circuit. An operational transconductance amplifier makes a good basis for our Vol-Expander since it is essential that the expansion is applied gradually, and is not virtually switched on and off. A voltage-controlled amplifier (VCA) using an operational transconductance amplifier tends to naturally give a suitable control characteristic. The circuit diagram of the Volume Expander is shown in Figure 13, and the operational transconductance amplifier used in the unit is a LM13600N device (IC1). This device has a number of additional features when compared to a basic device such as the CA3080E, the most obvious one being the fact that it is a dual device, and only one section of the device is used.

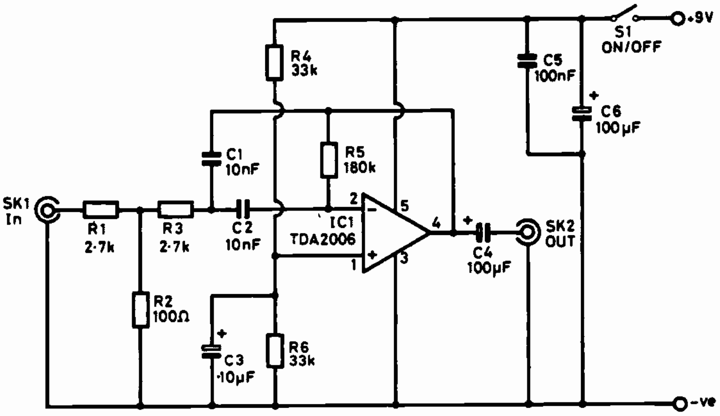

Fig. 13—Circuit diagram for Vol-Expander.

The other additional features of the LM13600N are the inclusion of a Darlington pair-emitter follower stage for use at the output of each section of the device, and linear diodes at the input of each section. The linear diodes can be fed with a small bias current, and this enables the device to handle a significantly higher signal level (about 10 dB in fact) before serious distortion occurs. This enables a higher overload margin and (or) increased signal-to-noise ratio to be achieved.

Resistor R8 is the discrete load resistor for the internal buffer stage of IC1, and R6 provides the bias current for the linear diodes. R7 sets the quiescent voltage gain of the circuit at a little under unity.

Some of the input signal is coupled by C4 to the input of a common-emitter amplifier which utilizes Trl. The amplified output from Trl is coupled by C5 to a rectifier and smoothing circuit which produces a positive bias voltage which is roughly proportional to the input signal level. This signal is applied to the amplifier bias input of IC1 via R12.

If only a low input-signal level is present there will be little or no current flow through R12 and into the amplifier bias input of IC1, and the voltage gain through the circuit will not be significantly changed. At higher signal levels the bias potential produced across C6 becomes large enough to produce a significant current flow through R12, and the gain of the circuit is boosted somewhat. At high signal levels of around 500 mV *rms*, the bias voltage becomes high enough to produce a boost in gain of around 12 dB. This is about the maximum expansion that can be used without the signal processing becoming obvious.

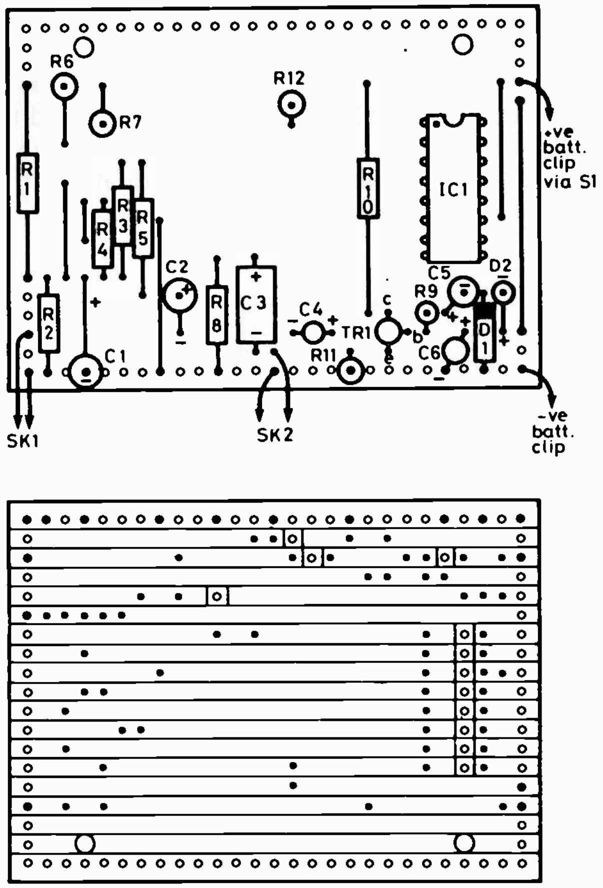

Fig. 14—Construction details of the Vol-Expander.

Capacitor C6 has been given a fairly low value so that the attack and decay times of the circuit are both fairly short, and the unit responds very rapidly to changes in the input level. However, the attack and decay times are made sufficiently long to prevent significant distortion from being produced.

The current consumption of the circuit is only about 6 mA, and a small 9-volt transistor-radio battery makes an economic power source.

Suitable aluminum cabinet or box, 0.1-in matrix stripboard or perf-board, two RCA phono jacks (SK1 and SK2), 9-volt transistor-radio and battery-clip connector, wire, solder, etc.

Construction. An 0.1-in. matrix stripboard panel for the Vol-Expander is detailed in Fig. 14, and a board having 19 copper strips by 27 holes is required. If you cannot obtain this board, a perf-board of the same size with flea clips inserted may be used. Interconnect the flea clips with No. 22 copper wire. Jacks SK1 and SK2 are the popular audio RCA phono types on the prototype.

If a stereo expander is required, it will be necessary to make up two boards, one to process each stereo channel. Alternatively, a longer piece of stripboard or perf-board could be used, and the otherwise unused section of IC1 could then be used as the basis of the additional expander circuit. The power supply center tap provided by R1, R2 and C1 could be used for the additional expander circuit, but all other components (apart from IC1 of course) would need to be duplicated in the extra expander circuit.

The Vol-Expander circuit should give good results if fed with the output of a tuner, cassette or tape deck, or a record deck via a suitable preamplifier. Some items of equipment might be found to have too little output to drive the circuit properly, and it will then be necessary to reduce the value of R11, or to even replace it with a shorting link. It is just possible that some signal sources will provide too strong a signal so that the expansion commences at a fairly low level, and in such cases R11 can be increased in value. If preferred, R11 could be replaced by a 1000-ohm linear potentiometer which would be adjusted for (subjectively)the best results.

COMPUTER VOICE

Need a mechanical-sounding voice, often called a "computer voice"? Well, here's a simple circuit that can be put to good use in amateur dramatic productions, telephone message tapes, etc. It's easy to produce synthetic- or computer-type voice effects from an ordinary voice-signal input. There are several ways to generate this effect, but probably the simplest method that gives good results is to amplitude modulate the ordinary voice signal by using a squarewave as the modulating signal. This is similar to the well-known tremolo effect which is sometimes used with guitars and other electronic instruments, but tremolo units normally use a triangular or sinewave modulation signal to give a smoother form of modulation. In this application a squarewave gives better results, and a sinewave or triangular waveform would be less effective. The unit switches the input signal between being passed straight through to the output, and being attenuated by around 20 dB, or so. A switching rate of a few Hertz is used.

The Circuit. The circuit diagram of the Computer Voice unit is given in Fig. 15. It consists of two sections: an oscillator to provide the modulation signal, and the modulator itself.

The oscillator uses a 555 timer chip in the astable multivibrator mode, and the frequency of operation has been set at about 10 Hertz by the values given to R1, R2 and Cl. The mark space ratio (duty cycle) is virtually one to one as the value of R2 has been made high in value relative to the value of R1.

Aluminum case, solderless or perf-board circuit board, 9-volt transistor-radio battery and matching battery clip, two 3.5-mm jack sockets (SK1 and SK2) or reasonable substitute, wire, solder, etc.

A very simple modulator is used, but this is quite all right in this application where a small amount of distortion is quite acceptable. Distortion produces new frequencies that help to change the voice signal and make it sound less like the original. A large amount of distortion is obviously not desirable as it would severely impair the intelligibility of the output signal.

Transistor Tr1 is used as a sort of voltage controlled resistor: and, in conjunction with R4, it forms a voltage controlled attenuator. Capacitor C4 is merely a DC blocking capacitor at the input and R3 is used in the base circuit of Tr1 to effectively make Tr1 a voltage-controlled device rather than a current-controlled one. During the periods when IC1's output is high, Trl is biased into conduction by the base current it receives via R3, and effectively has a collector-to-emitter resistance of only a few hundred ohms. This gives losses of around 20 dB or so through R4, and attenuates the signal fed to the output by this amount. When IC1's output is low, Trl is switched off and the input signal can pass straight through R4 to the output. The only attenuation is due to the potential divider action between R4 and the input impedance of the equipment to which the output signal is fed. This should minimize losses.

Thus the output signal is switched up and down in amplitude, producing the required computer-type voice effect. Capacitor C3 is included in the circuit to slightly slow down the sharpness with which the signal is switched between the two levels of gain, and this helps to avoid "clicks" which can otherwise occur during transi-

tions from one gain level to the other. Capacitor Cl is a power-supply decoupling capacitor and this also helps to prevent switching "clicks" from being generated within the unit.

Construction. It is advisable to assemble the project on a solderless circuit board as illustrated in Fig. 16. Assembly is easy and experimental changes in component values will enable you to customize the output voice signals to your taste. Jack sockets (3.5-mm) were used for SK1 and SK2 on the prototype but these can be any two-way audio connectors. It is a good idea to house this project in an aluminum metal case (grounded to the negative supply rail of the circuit) so that the circuitry is screened from power-line hum, radio frequency signals, and other possible sources of electrical interference.

The unit can be used to process a signal directly from a microphone, but this may well cause problems with large losses through the unit even when Tr1 is in the off state. This loss is due to the fact that some microphones are designed to feed into quite a low impedance, and with such a load-impedance mismatch substantial losses occur. Some microphones are designed to feed into high impedance and will not produce this problem. Nevertheless, as microphones of this type have quite a high impedance, the losses provided by the unit when Trl is in the on state will be much higher than is really desirable. There is also the problem of the low-output level of a microphone that requires a high level of gain from the unit. This amplification will also boost the noise level to an uncomfortable listening level.

It is better to feed the microphone signal to the unit via a preamplifier, so that a fairly high-signal level is fed to the unit. A mere one stage of isolation with attending load matching is invaluable here.

There should be no problems if the unit is fed from a tape recorder or some piece of equipment which provides a similar signal level (a few hundred millivolts *rms*). It is not advisable to use the unit to process a signal having an amplitude of more than about 1.0 volt *rms* as quite severe distortion could then be produced.

10 Audio Power Booster

Despite the fact that there is a fair amount of noise inside most cars when they are traveling, many car radios and tape players have rather insufficient output powers to play over road noise. One reason for this is probably the fact that it is not possible to obtain a great deal of power using a 12-volt DC supply and a modern transformerless output stage into a 4- or 8-ohm loudspeaker. The maximum possible output swing is nominally 12 volts peak-to-peak. No output stage gives an output voltage swing equal to the supply voltage as there are inevitably voltage drops through the output transistors. On the other hand these are counteracted to some extent by the fact that a car battery usually has an actual voltage which is somewhat more than its nominal level. In terms of *rms* voltage this limits the maximum output to only about 4.25 volts, which gives only about 2.25-watts *rms* into an 8-ohm speaker, or 4.5-watts *rms* into a 4-ohm type.

There are ways of obtaining increased output, and the method used in the Audio Power Booster is to use a bridge-amplifier circuit. The Audio Power Booster is connected between the car radio or tape player and the loudspeaker, and it gives an output power boost of about 9-watts *rms* into an 8-ohm load or 18-watts *rms* into a 4-ohm load.

A Bridge Does It. A bridge-amplifier circuit consists of two power amplifiers with the loudspeaker being driven from the two outputs; neither speaker lead being connected to the car's chassis ground. The two amplifiers are arranged so that under quiescent conditions their outputs are at the usual level of about half the supply voltage, and there is no significant voltage present across the loudspeaker. The amplifiers are arranged to have output signals that are in antiphase, so that a positive change in the output potential of one is matched by a similar but negative change in the output voltage of the other. Thus when one amplifier has its output fully positive, the output of the other one is fully negative. This gives about 12 volts across the loudspeaker. On signal peaks of the opposite polarity the two output states are reversed so that 12 volts is again

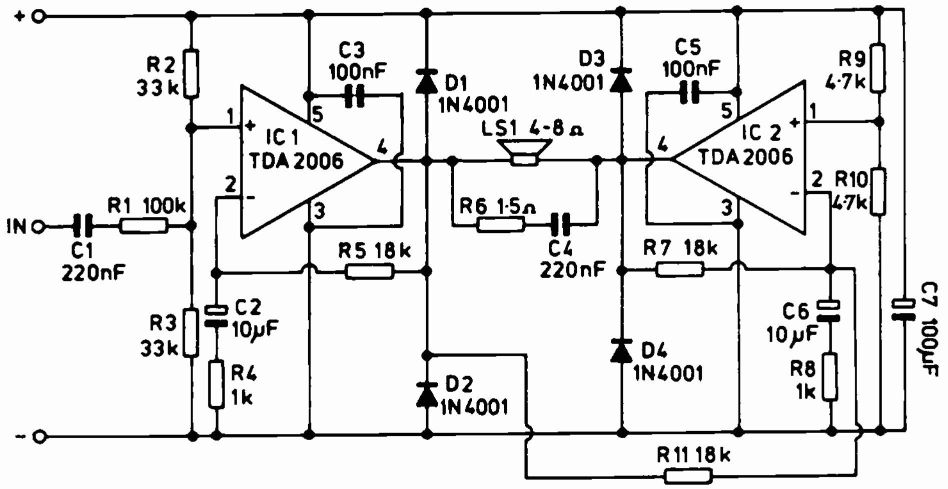

Fig. 17—The circuit diagram of the Audio Power Booster. Notice the almost mirror image of the circuit components surrounding the ICs.

developed across the loudspeaker, but the polarity of the output signal has changed. Thus the amplifier can give up to ±12 volts across the loudspeaker, or a peak-to-peak voltage swing of 24 volts. This is double that obtained with a normal amplifier, and gives a maximum output current that is also doubled; thus the output power for a given speaker impedance is boosted by a factor of four when compared to an ordinary audio power amplifier.

The Circuit. The Audio Power Booster is based on two TDA2006 audio IC power amplifiers, as can be seen from the circuit diagram of Fig. 17.

Power amplifier IC1 is used as what is virtually a non-inverting amplifier, with the non-inverting input of the device being biased to half the supply voltage by R2 and R3. R5 provides 100-percent negative feedback from the output to the inverting input of IC1 at DC so that the circuit has unity voltage gain and the output is biased to the required level of half the supply voltage. C2 and R4 remove some of the feedback at audio frequencies and this gives a voltage gain of about 18 times at these frequencies. This is far more than is actually needed, and a voltage gain of little more than unity is in fact sufficient. It is necessary to remove a substantial amount of feedback though as instability is otherwise likely to occur. R1 is used at the input of the amplifier to reduce the sensitivity to a more suitable level, and C1 simply provides DC blocking at the input.

IC2 is used in virtually the same configuration, but its non-inverting input is not fed with an audio signal, and only receives the DC bias signal from R9 and R10. Resistors R2, R3, R9 and R10 are all close tolerance components so as to ensure a reasonably small voltage difference across the outputs of the two amplifier stages under quiescent conditions; and, consequently, a small and insignificant quiescent current through the loudspeaker. Resistor R11 couples the output signal of IC1 to the inverting input of IC2, and the value of R11 is chosen to give IC2 an effective voltage gain of unity. However, as the input signal is coupled to IC2's inverting input there is a phase inversion through this section of the amplifier, giving the required anti-phase relationship at the two outputs.

Diodes D1 to D4 are protection diodes for the two ICs, while R6 plus C4 form a *Zobel* network which helps to prevent instability. Components C3, C5 and C7 are all supply decoupling capacitors.

Construction. A 0.1-in. matrix stripboard having 18 copper strips by 17 holes is used to accommodate most of the components, and the component layout of this board is given in Fig. 18. There are no breaks in any of the copper strips. The audio power ICs are modern types which physically resemble plastic power transistors, but they have five rather than three leads. These must be carefully bent apart slightly in order to fit these devices into this stripboard.

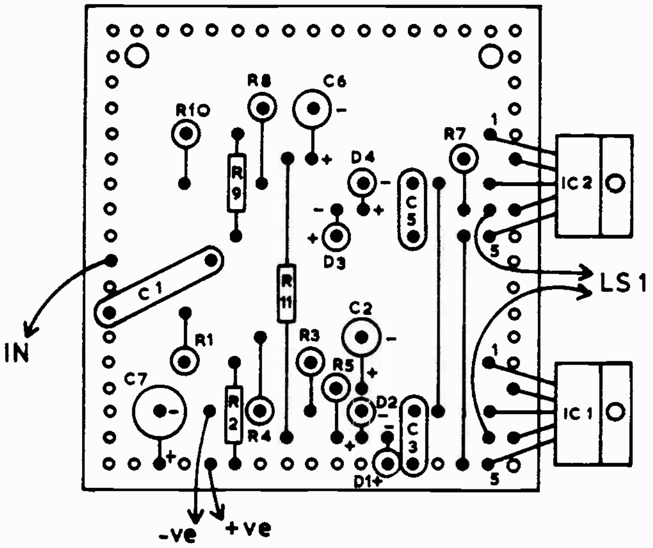

Fig. 18—Component layout for the Audio Power Booster as placed on a 0.1-in. matrix stripboard. The copper strips (on the reverse side of the board) run horizontally from left to right. If perfboard is used, interconnect all leads on the common horizontal row of holes for each strip.

Ensure that you do not omit the two jumper (link) wires. Be very careful to connect the polarized components with the correct polarity, especially the four rectifiers as these could be damaged or cause damage if connected incorrectly. Use the same care with electrolytic capacitors.

The two ICs should be bolted to a substantial heatsink. If the unit is used in a negative ground vehicle it can be fitted into a metal case which can be used as the heatsink, but it will probably be necessary to use an aluminum bracket to provide a thermal path from the ICs to the case. A suitable bracket can easily be produced from #18 *swg* aluminum that is commonly used in manufactured chassis boxes.

In positive ground cars this is not really advisable since the heat-tabs of the ICs connect internally to their negative supply readouts. This would result in the case connecting to the negative supply, and the likelihood of a short circuit between the case of the booster and the positive chassis of the car. Insulation sets supplied with the semiconductors can be used to insulate the heat-tabs from the case. Do a careful job since vibrations may shake the parts apart

Components R6 and C4 are not mounted on the component panel, but are wired across the output socket or terminals of the Audio Power Booster.

When installing the booster remember that neither output lead should be allowed to come into contact with the chassis of the vehicle. The TDA2006 incorporates output short-circuit protection circuitry and thermal overload shutdown circuitry, and accidental contacts between the output leads and the chassis (or each other) should not damage the unit.

Power. The power supply voltage for the unit should be taken from the supply line of the radio or tape player with which the booster is employed, as it will then be switched on and off with the main item of equipment. However, the unit can have its own on/off switch added into whichever supply lead is not grounded. The input for the booster is taken from whichever output lead of the radio or tape player is not grounded, and the correct lead can be found simply by connecting the two leads, in turn, to the input of the unit to see which one provides the desired result.

If the unit is used with a radio or tape player that has only a very limited output power it may be necessary to reduce R1 in value somewhat in order to fully drive the booster.

11 Pit-Stop—The Indy of Electronics

Pit-Stop is a motor-racing game that can be played with up to four competitors, the winner being the first driver past the checkered flag after a pre-arranged number of laps. The rules are simple and to the point. A driver can move away from the starting grid only when he has tanked up. Fueling and moves (distance round the track) are determined by an electronic indicator, the number of moves depending on skill in selecting the numbered LEDs that flash in sequence. Each move results in fuel being used up and the state of each fuel tank is monitored by a FUEL GAUGE. Lack of fuel is shown by the TANK EMPTY indicator light; drivers must then stop to TANK SELECT and refuel before any further movement. In addition to the DRIVE and REFUEL operations, there are hazards and advantages along the track dictated by game cards.

Pit stops can be enforced by game-card selection and, in a more realistic version of the game where refueling is confined to the pits, also made at a driver's discretion. If this rule applies, a TANK EMPTY light on when the car is out on the track puts the driver out of the race.

The Circuit. The circuit diagram for the Pit Stop game can be considered to consist of four basic blocks:

- counter;
- the decade counter and ten-LED flashing display that can be stopped momentarily to indicate either REFUEL or DRIVE distance outputs, selected by the players;
- four tank capacitors, chargeable when tank-up switches are pressed;

- the comparator, controlling the TANK EMPTY light, and a meter that monitors fuel levels.

In Fig. 19 the clock generator, which provides the timing pulses for controlling the decade, the clock generator, IC1, is the popular CMOS 555 timer used in the astable multivibrator mode. The frequency of oscillation is controlled by the fixed capacitor Cl, and the variable resistor VR1 (SPEED). Output pulses are available at pin 3.

The 555 output of IC1 is directly coupled to the clock input of integrated circuit IC2, a 4017 decade divider/counter. With the reset output (pin 15) connected to the 0V line, the ten LEDs (D1-D10) connected in the divider outputs flash sequentially at a speed determined by the setting of VR1. Normally, VR1 is set so that the counter output LEDs flash at several times per second. During a turn by a player, when S1 is pressed, contact Sla freezes the display on one LED for a few seconds before flashing resumes. The rate of flashing should be fast enough so that some skill is required to anticipate the selection of a particular LED. However, for younger players, it may help to select a slower speed with VR1.

Fig. 20—Circuit diagram for the Pit-Stop fuel-tank and comparator circuit.

As shown in Fig. 20, each player has a tank (electrolytic capacitors C3-C6) that can be charged via a TANK-UP switch (S4-S7). Four of the outputs of the counter are coupled via resistors (R3-R6 on Fig. 19) to the TANK-UP switches. During refueling, when a selected output is frozen for a few seconds, if the relevant TANK-UP switch is pressed, the positive voltage on the output pin is connected via the 47,000-ohm resistor (R9) and switched to charge the driver's tank capacitor. If by misjudgment another driver's LED is selected, then the other driver can press his or her TANK-UP button and take on some fuel.

Before pressing the GO switch S1, the TANK SELECT switch S2 must be set to the player's position. Diodes D15-D18 isolate the tank capacitors and prevent any short-circuiting of charges if the rotary contacts of S2 should make-before-break. Switch S2 connects the comparator (IC3) and fuel meter (M1) to monitor the state of the player's fuel tank capacitor. It also connects the tank capacitor to a discharge circuit, when S1 is pressed, formed by R10 and C8 connected in parallel. On each turn, a player's tank is discharged slightly by this circuit, i.e. fuel is used up on the drive, especially if short distances are selected. Switch S3, DRAIN TANK, serves two purposes: it can be used with a Hazard Card to simulate a loss of fuel situation, or (at all positions of the TANK SELECT switch) to drain tanks for the next game.

Diodes D11 to D14 enable tank capacitors to be charged via the TANK-UP pushbuttons if the ALL refuel light is on.

The comparator is a 741 operational amplifier, IC3, which monitors the voltage in a tank capacitor and compares it with a reference voltage set by potentiometer VR2. When the voltage level in the connected tank capacitor falls below the reference voltage, output pin 6 of the comparator goes high; this switches on transistor Tr2 and the

TANK EMPTY LED lights. A TANK-UP operation is then required.

Switch S2 also connects the fuel meter circuit to a driver's tank circuit for monitoring purposes. Transistor Trl is connected as an emitter-follower, the high-input impedance preventing excessive drain on the tank capacitor. The fuel reading on the micro-ammeter (M1) in the emitter circuit is set by the series preset resistor VR3. Leave the setting for VR3 in the maximum resistance position. This will prevent the meter from being damaged when the game is first turned on.

Construction. The prototype was constructed on a 15-in. square, 3-ply board, layout as shown in Fig. 21, with four 2-in, xxX 1/4-in strips for the sides. The clock generator and decade counter were mounted on a separate piece of 0.1-in stripboard or perf-board. A perf-board with flea clips may be used or a solderless breadboard and later converted to a matching pre-etched circuit board with components soldered in place. The wiring is not critical, but neatness is important should troubleshooting be required.

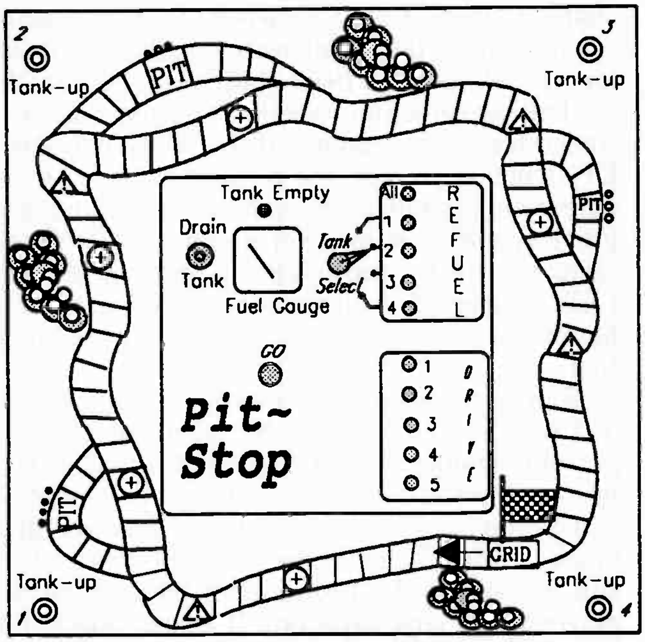

Fig. 21—Suggested Pit-Stop game board layout. The final layout is limited only by your imagination.

The track layout can be an enlarged replica of the one shown in Fig. 21, or can be modified to incorporate other ideas, especially if the constructor is a motor-racing enthusiast.

Playing. If you drive a car, a quick briefing on the play philosophy is all you will need to understand the game.

1. Before starting, set the battery switch S8 on and make sure that the four fuel tanks are discharged by pressing the DRAIN TANK switch S3 while rotating the TANK SELECT switch S2.

2. Set the SPEED potentiometer VR1 to an agreed speed.
3. Select in turn to decide order of play by highest drive positions, and which two cars will be in pole (front) positions.

NOTE: Only two cars can be abreast at any time during a race, so a third car coming up fast behind two cars on the same patch of track will have to tuck in behind and forfeit any extra distance selected for the move.

4. The driver in pole position starts by switching the TANK SELECT switch to his position (RED, BLUE, YELLOW or GREEN). For instance, when the RED switch position is selected as shown, the red driver tries to anticipate when the LED for the red output is on and presses GO momentarily to select it. If successful, he then presses his TANK-UP switch to charge up his tank only while the LED remains on. Successful fueling is indicated if the TANK EMPTY lamp goes off, and a driver can select a drive distance when the next turn comes round, or elect to tank-up further.

5. The next driver in pole position, switches the TANK SELECT switch to his position and tanks-up in the same way.
6. The two drivers on the back row of the starting grid follow suit, but cannot drive off until at least one driver in pole position has moved (the no-passing two rule).

> **NOTE:** Holding down the TANK-UP switch after flashing resumes will result in some loss of fuel.

7. At the beginning of a turn, on TANK SELECT, if the TANK EMPTY light is on, a driver must tank-up. Any DRIVE moves selected inadvertently are forfeited.
8. If the ALL position is selected, all drivers can press their TANK-UP button to take on fuel.

Game Cards. Game cards are of two types—hazard and advantage. When a car lands on a hazard square (indicated by a triangle) the player draws a Hazard Card and obeys the instructions on the card. Likewise, an Advantage Card is selected whenever a car lands on an advantage square (indicated by a circle). Cut a number of cards to the size of business cards. Leave one side blank and on the other side type or write the following:

Hazard Cards
- Oil spill-lose a turn.
- Spin off track-lose a turn!
- Slow-down for chicane-reduce drive by 1.
- Tank holed-press DRAIN TANK.
- Aqua-planing-compulsory pit stop to fit wet tires. Lose a turn.
- Engine overheating-compulsory pit stop. Lose one turn.
- Flat tire-reduce drives by one and one compulsory pit stop.

Advantage Cards
- Super-fuel!-add 2 to drive score.
- Engine finely tuned-up-add 1 to drive score.
- Following wind-double drive score.
- Reserve tank-perform TANK-UP.
- Double accelerate-hold card until needed.
- Close gap-tuck in behind car immediately in front.
- Good road-holding-hold card and add 1 to drive score on next bend.

If you wish, let your imagination add additional hazards and advantages to the game cards you make.

The playing pieces for the board game may be pawns from a discarded chess set or some other easily gripped object. Coins are too difficult to manipulate. Paint the playing pieces appropriate colors to reduce confusion. Now then, drivers, man your cars!

12 Minefields

You are the captain of two ships that must navigate through magnetic minefields, racing against other ships in order to enter your safe port first. The game can be played by up to four players, each with two ships. In turn, under electronic control, the ships are steered past minefields in the direction of the home port. Refer to Fig. 22 for the board layout. The eight minefields normally flash sequentially (free-run) to warn ships of danger, until a mine is detonated (glows steadily) by a player.

Depending on the players' temperament or the state of the race, some players may take the longer safe channels (unless under other orders), while other captains may risk a winning dash for the home harbor via the minefields.

Movement. Players move in turn by pressing their DETONATE pushbuttons, which freeze the flashing minefield display for a few seconds. This results in one of two situations, as follows:

1. On detonate, one of the eight mines will glow for a few seconds together with one of the navigation lights. The player will observe which of the navigation lights is on, and also check if there is a ship lying on one of the eight shaded squares that surround the glowing mine. After the player has made his move, any victim in the minefield must either return his ship to base in the case of a direct hit (dark square) or take a NEAR MISS game card (gray square) and act upon instructions.

With regard to the direction of play, Fig. 23 shows the four moves. These are made in relation to a player's starting direction shown next to the DETONATE button:

- A green (starboard) light indicates a forward diagonal turn to the right.
- A red (port) light indicates a forward diagonal turn to the left.
- AHEAD indicates a forward move directly towards the harbor.
- ASTERN indicates a backwards move directly towards the base.
- A ship is only moved one square at a time, unless a game card instructs otherwise.
- Ships cannot be moved sideways.

2. If a mine does not remain on after a DETONATE, then one of the two center LEDs ACTION STATIONS or NEAR MISS will glow.

If it is a NEAR MISS light, then the player will take a NEAR MISS game card and act on it. However, in the event of ACTION STATIONS, all players are at liberty to press their DETONATE button as soon as the display returns to free-run, primarily to ward off any danger or to create havoc. The player will then take a game card from the ACTION STATIONS pile and act on the instructions. Game cards can sometimes be held for future use if not valid. In this case, they will take the place of a turn. After use they will be returned to the bottom of their respective piles.

The SPEED control (VR1) can be panel-mounted if desired and marked for half-speed and full-speed settings to cater for younger children, and for special instructions, e.g. on ACTION STATION game cards.

Depending on the agreed speed and a certain amount of anticipation, the display can easily be frozen on a desired mine, or navigation direction to shorten a game.

If a move cannot be made for any reason, e.g. obstacles such as coast lines, other ships, mines, then the move is forfeited. A move can be made by either of a player's two ships when thought advantageous, e.g. to hold direction or to avoid a minefield.

Hazards. One of the eight mines can be detonated (permanently lit): by a player's DETONATE switch as a normal turn, by detonating after the ACTION STATION light comes on, or if an ACTION STATION game card says DETONATE.

Any ships in a minefield when it is detonated (one mine permanently on) either take instructions from the top NEAR MISS game card if in the light-shaded square or if a DIRECT HIT is registered (on a dark square) go back to base for repairs.

The HALF SPEED and DETONATE game card introduces an element of skill. It allows more time for a player to anticipate which mine shall be detonated. The player operates the HALF SPEED button to slow down the display before detonating. This gives a chance to inflict a direct hit or a near miss on any rival ships already in a minefield.

The SPEED control can be reduced for the first few games, or to assist younger players; alternatively, younger players could use the

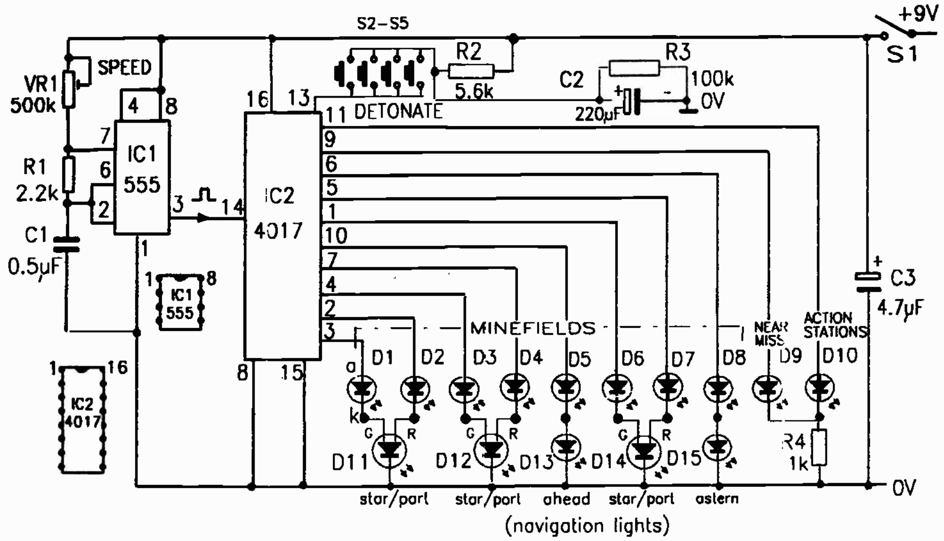

Fig. 24— Circuit diagram of the Minefields circuit.

HALF SPEED control for each move.

Ships may not enter an opponent's HARBOR.

Circuit. The 555 timer can be varied by VR1 to give a suitable speed for the free-run display for the mine and navigational LEDs. Refer to Fig. 24. The inclusion of three tricolor LEDs in series with the minefield LEDs gives green (starboard) and red (port) navigation signals. Also, the electrolytic capacitor C2 together with resistor R3 provides a time constant to hold the detonate and navigation information for a few seconds for scrutiny after a DETONATE push-button is released. This time can be lengthened or shortened as desired by altering the value of capacitor C2 (reduce capacitor value to shorten time and vice versa).

Layout is not critical, but requires a minimum of woodworking skill. The circuit elements can be soldered rats-nest style or assembled on pre-etched circuit boards and solderless boards. Neatness will make troubleshooting easier.

13 Building the Kapellmeisters

Most transmission-line loudspeaker enclosures involve a lot of tricky woodwork so that many speaker builders with only modest woodworking skills are deterred from building one. With the Kapellmeisters, although quite a lot of woodworking is needed, none of it is difficult, mostly it consists of cutting straight edges. These edges must be straight though, so if your saw cuts tend to wander, get the lumber yard to cut them for you. The measurements are uniform with many pieces being identical.

Preparation. Ceramic tiles used in the construction of the Kapellmeisters are standard 8- × 4-inch, cut down to 7 × 4 inches. That is just one straight cut per tile. The exception is the top tile over the speaker which because of its different angle must be narrower, 7 × 3.5 inches.

Triangular wood blocks are used to support the tiles. These are made by first cutting four 3-inch squares, then sawing diagonally to give eight triangles. The two wood blocks for the over-speaker tile are made by halving a 30- × 2-inch rectangle along the diagonal.

A standard 3 ×1 mix of sand and Portland cement (we will call it concrete) is used to fill the space behind the tiles. The concrete is applied between the blocks and the tile bedded on to it.

In all cases screw two or three stout wood flathead screws at random angles into the wood where the cement is to be laid leaving about an inch out of the wood, so that the protruding head of the screw will be buried in the concrete. These screws will then secure the concrete block in place when it is dry. Thoroughly wet the back of the tile before applying it to the concrete. In some cases the front of the tile may need to be held in place while the concrete sets, with wood panel nails knocked into the wooden sides. It does no harm to leave them there afterward.

All jointing is done by a strong wood glue. Elmer's wood glue was used for the prototypes which is very strong and convenient to apply; however there are many suitable wood glue alternatives on the market. The glue also fills any small gaps where the saw might have made a slight rough cut. Construction must proceed in numerous stages to allow the glue and concrete to set before continuing with the next stage, so some patience must be exercised. Make both speakers at the same time so that each stage can be completed on both and thus save time.

First Stage. Refer to the diagram of wood panels (Fig. 25), and buy sufficient plywood for all pieces. Remember that these pieces are for one speaker, so each unit will have to be duplicated. As so many are just 3-in. strips, it is likely that much can be obtained as scrap cuts. Most large lumber yards sell these at a reduced rate, and the color or grade doesn't matter as all are concealed except the top and bottom cheeks. The thickness should be as specified, 3/8 inch for the sides, baffles and back, 1/2 inch for the front, and

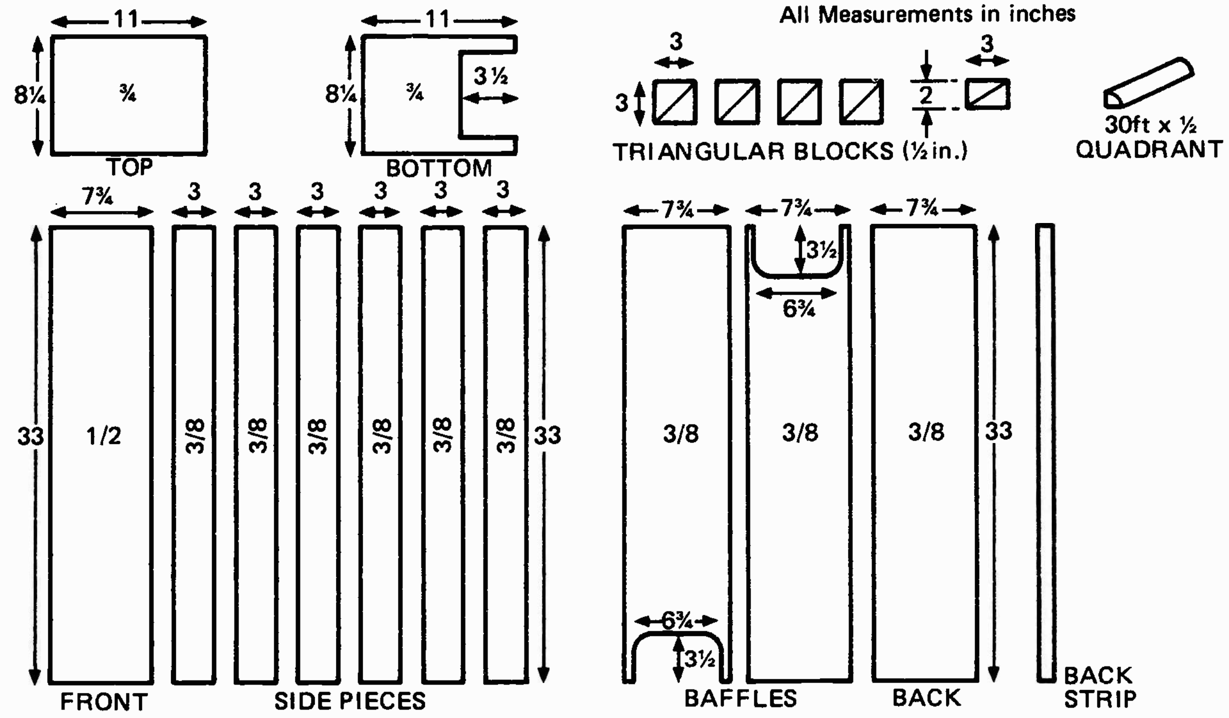

Fig 25 —View of all the wooden parts for one speaker cabinet including dimensions. Each side of the cabinet is made of three parts requiring a total of six side pieces for one speaker. All pieces should be plywood. See text for addition details on materials.

3/4 inch for the cheeks. It really will save a lot of time and energy if you get the lumberyard to cut the pieces with his machine saw. They usually charge slightly for each cut.

The lumber yard probably will not do the shaped ports at one end of the baffles and bottom cheek, but this can be managed with a fret or copping saw. A 7-1/2 × 4-1/4-in. elliptical speaker hole should be cut in the front panel starting 21 inches from the top. Before you cut the hole, check the physical size of the loudspeaker. It may be slightly different. It is desirable though not essential for the hole to be beveled outward.

Loudspeaker. A word about the loudspeaker that you should select. An oval speaker was selected for the original unit and it was rated at 8 watts with pretty good specifications at a low price. You should do the same; however, that would take away the fun of redesigning all project builders get involved with. Keep in mind that as the price goes up, the increase in performance lags behind so that dollars are wasted. Keep in mind that the Kapellmeister is designed to bring the best out of inexpensive loudspeakers.

Second Stage. Start with the front panel; lay it face down supported on some scrap quarter-inch ply or hardboard. Glue the top and bottom edges and fit the top and bottom boards. The front edges of the top and bottom cheeks should *not* rest on the ply supports but directly on the work surface; they will thus protrude a quarter of an inch beyond the panel. Refer to Fig. 26(a). The top and bottom cheeks should also be positioned to give an equal overlap at either side. The idea is for the top and bottom cheeks to overhang the front, sides and back 1/4-in. from all sides.

Weights should be applied to the free sides of the cheeks to hold them against the panel while drying. Measure the distance between the rear edges of the top and bottom cheeks to ensure that it is exactly 33 inches and therefore the top and bottom are parallel. Wait for glue to set and harden.

Third Stage. Fit the first pair of side pieces, gluing the ends and the edge contacting the back of the front panel; ensure the pieces are flush with the edge of the front panel. Measure across the upper edges to make sure they are 7-3/4 inches and so are true. Now glue the triangular blocks in place at the bottom and top as shown in (a) of Fig. 26, the top ones being the special sized ones. Glue the edges as well as the face that contacts the sides, but be careful in pressing them into place that you do not move the sides. Wait for the glue to set.

Fourth Stage. Now fit the speaker, screwing it in place over the aperture, and connect by soldering a pair of wires which are run down the panel to a hole drilled in the bottom. Leave a few inches of free wire outside the cabinet, and make sure both speakers are connected the same way to the color-coded wire. After the wires are installed, fill the drilled hole for the wires with a mixture of saw dust and wood glue to seal the hole airtight and secure the wire in place.

It is prudent to cover the front of the speaker with a piece of stiff cardboard secured by masking tape or staples to protect the cone from accidental damage.

Fit several screws to the bottom and top cheeks between the triangular blocks, leaving about an inch protruding at different angles. These will be embedded in the concrete when it is applied and so will hold the resulting concrete wedge in place. Next fill the space between the bottom blocks with cement (not too wet) and bed the trimmed tile onto it. Place the top narrow tile on the blocks and fill in behind it with cement.

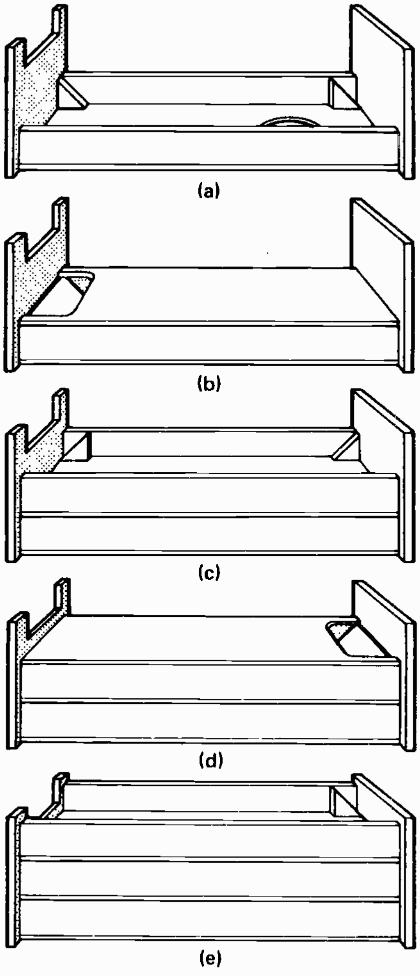

Fig. 26 — The vies a through e show the assembly procedure for the Kapellmeister. (a) First stage in construction. The front is glued to the top and bottom cheeks., using 1/4-in. supports to lift front panel to correct position. First pair of side pieces fitted and triangular blocks (small ones at the top) in position. Then apply concrete, fit tiles and lay wadding. (b) Fix in place first baffle, gluing down to insure close fit. (c) Fit second pair of side pieces and four triangular blocks (all blocks installed hereafter are regular size). Install tiles, concrete and wadding. Tuck extra lengths of wading through aperture into first channel. (d) Fit second baffle in place. Aperture goes at the top. (e) Glue in third pair of sides and last pair of triangular blocks. Fit tile and concrete and install wadding with extra length going into the aperture. Install the back panel (not shown). Refer to text for complete details.

Fifth Stage. Saw suitable lengths of 1-2-inch round molding (quadrant) and glue into the corners between the front panel and the sides. If they are warped they should be held in place with panel nails. Glue two additional strips of 1-2-inch round molding at the top inside edge of the sides and nail in place.

Cut three lengths of 1-inch thick acoustical wadding to size and lay them in the cabinet so that two start at the bottom of the speaker, and the third lies over it to the top of the case. (You can substitute roof/wall glass-foam 3-1/2-in. insulation for the acoustical wadding. Remove the insulation from its paper backing.) Fill the space above the speaker with a rolled up piece of wadding. Do not compress the wadding. Make the lengths a few inches longer so that they bend up at the bottom over the tile. Drops of wood glue or any quick-drying cement will hold the wadding in place.

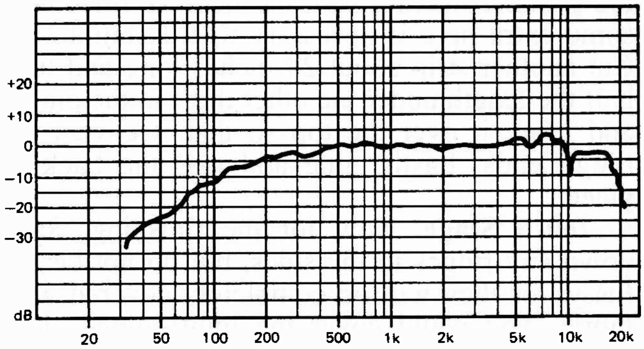

Fig. 27—Curve of the Kapellmeister speaker system frequency response. Some bass boost by the amplifier will straighten the curve at the low end.

Now fit the first baffle with the cut-out at the bottom, gluing to the top edge of both the sides and the upper 1/2-inch round molding surface. Also glue to the top and bottom cheeks. Secure with wood panel nails to ensure a close fit as (b) in Fig. 26. Next, fit the second pair of side pieces and two pairs of blocks top and bottom, (see c). Fit 1/2-inch round molding to corners as with the first channel, also to top edges of the sides; wait for all the glue to dry.

Sixth Stage. Fit the tiles and cement as with the first pair, not forgetting to use concrete-securing screws to top and bottom cheeks in the area to be filled with concrete. This time the top one will be bedded and the bottom one rear-filled. Wait for the concrete to set.

Seventh Stage. Cut two pieces of acoustical wadding about 18-inches long and push half the length of each up the lower channel through the cut-out, and lay the other half length back along the top channel. Now lay three full length strips over these along the complete upper channel. This gives the extra density at the first bend needed to dampen the third-harmonic antinode.

Next comes the second baffle which is glued and nailed as the first but with its cut-out at the top as shown at (d). Fit the third and final pair of sides, also the last pair of blocks plus the 1/2-inch round molding in the corners and top edges, see (e). Allow glue to harden,

Eighth Stage. Now for the last tile, again not forgetting the screws in the top to secure the concrete wedge. Mount the tile on the blocks using wood-panel nails to keep it in place; this will be easier if the enclosure is stood vertically upside down. Return to the assembly to the horizontal, and fill in rear with cement. Wait until set.

Ninth Stage. Lay three strips of wadding in the channel making sure the bend is filled. Put some extra here if necessary to fill completely. Cut another strip about 24-inches long and tuck half the length under the other three at the outlet, and bring it over the top so that it covers the rough ends. Lastly glue and nail the back in place.

Tenth Stage. Now for the finishing. Sand down any ridges in the sides, but do not be too fussy, for they will be completely covered with fabric. You could cover the multi-joined sides with a wood veneer, but it is not mandatory.

Check carefully for any cracks or crevices in the jointing and fill with the wood glue. Sand, then stain or varnish the top cheek and the edges of the bottom one; there is no need to do underneath unless you are fussy. Paint the body with flat black paint including the inside rim of the loudspeaker aperture, but be very careful not to get any paint on the loudspeaker cone as this would affect its flexibility. The painting ensures that the bare wood does not show through the grille fabric with which the whole body excluding the cheeks is covered.

The two back strips (one for each speaker) should now be cut to fit exactly between the top and bottom cheek rear overhangs. These strips conceal the join in the fabric covering so should be about one-inch wide preferably beveled at both edges to give a good finish. They should be stained or varnished the same color as the cheeks.

Eleventh Stage. Obtain sufficient black speaker grille fabric to cover both speakers. Any other color can of course be used if preferred and is obtainable.

Cut the fabric to the exact size to cover the body between the cheek overhangs, but leave a flap 4 inches longer and 8-inches wide, at the start. Secure the vertical starting edge at one edge of the back of the enclosure with tacks so that the flap hangs over the bottom. Then pull it around, keeping it taut, overlapping the start and securing it with one of the wooden strips down the middle of the back. This can be done with brass countersunk screws with cupped washers which give a professional-looking effect.

Next trim the flap to fit between the prongs of the bottom and fix it across the exit port with staples.

Twelfth Stage. Make or purchase two sets of 2-inch high, wood legs. A single rear one should be made to incline backward under the rear exit vent to give greater stability. They can be stained or varnished to match the rest. The Kapellmeisters are now complete and ready to go into action.

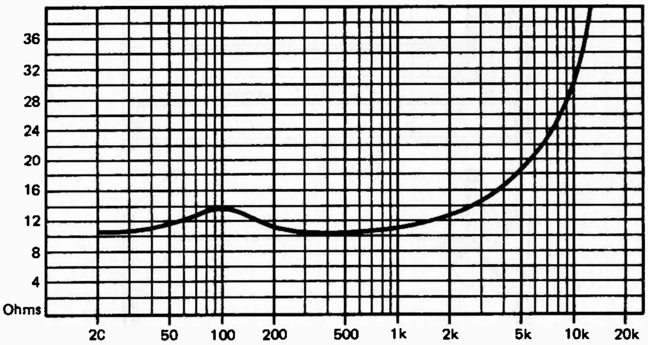

Fig. 28 — The Kapellmeister's impedance curve which is typical of projects using quality loudspeakers.

Performance. As an anechoic room was not available to test the Kapellmeisters, frequency response tests were made with the multiple-microphone-position technique. The test was repeated on the second speaker, and the results were very close, so the plot in Fig. 27 can be considered fairly accurate.

Surprisingly, the treble response is sustained beyond 16 kHz and actually continues up to 20 kHz, a remarkable achievement for a single-driver speaker with no tweeter. This is a tribute to the controlled flexure of the cone and the effectiveness of the high-frequency folded horn inside the cabinet. The undulations are fairly smooth, and some of the vicious peaks and dips encountered with certain multi-driver speakers are notably absent. The response is within 5 dB from 16 kHz to 200 Hz, apart from small deviations at 7 kHz and 10 kHz. There are no phase problems over any part of the range.

Of course the performance varies from loudspeaker type to speaker type, but when you start with a known-good loudspeaker the results will be good.

As expected, the bass is not sustained with a flat response to as low a frequency as would be obtained from a large infinite baffle or reflex enclosure. The response crosses the -5 dB level at 200 Hz and from there a very gentle descent, but audible output is maintained down to around 36 Hz. Actually, there is a 3-dB drop in the octave 500 to 250 Hz, a 6-dB drop from 250 to 125 Hz, and a 12-dB drop from 125 to 62 Hz and below. This gentle and gradually increasing slope results in a more natural and musical bass than when the roll-off is lower, but steeper. A further advantage is that this curve is ideal for applying a little bass boost at the amplifier. All bass boost controls hinge the response curve upward from a pivotal point at 1000 Hz. Frequencies just below 1000 Hz are hardly affected, but the amount of boost increases as the frequency drops. If bass is boosted with speakers having a steep roll-off, the frequencies just above the roll-off point are lifted to produce a hump, so resulting in a boomy effect. Here, bass boost will lift the curve to give a flatter response without boom.

Thus with a little boost in the bass, the single-driver loudspeaker in an enclosure only 8-inches wide can be made to give a response equivalent to that of a much larger multi-driver speaker, but without the phasing problems and distortions they and the crossover network produce.

The impedance curve is also of interest and is here shown (Fig. 28). There is no large peak in the bass, just a small rise at 100 Hz, which is at the third harmonic of the transmission line resonant frequency.

Bass peaks indicate a high back *emf* generated by a large cone movement at the resonant frequency, even though the acoustic output may be damped by the cabinet design. Often these excursions may be large enough to enter the non-linear region or even strain the cone suspension. In such cases bass boost should be applied cautiously and moderately if at all to avoid speaker damage, quite apart from causing a hump in the response as noted above. Here, having no impedance peak, there is no excessive cone excursion at any frequency and no such restraint is necessary. Bass boost can thus be applied to obtain a satisfactory balance without fear of damage, providing the speaker's power rating is not exceeded.

At the high-frequency end, the impedance curve gradually rises to 60 ohms at 20 kHz. This is not due to increasing cone movement but the increase of the coil reactance with frequency. This means that less power is being taken from the amplifier at these frequencies. As amplifier distortion often decreases with an increase of load impedance, this should present a very easy load for any amplifier, and there should be none of the unexpected problems often encountered when an amplifier takes a dislike to a particular speaker. Nowhere does the impedance fall below 10 ohms.

An amplifier of just a few watts may be used for full listening impact in a listening room. Five watts per channel should be sufficient and well within the, speaker's 8-watts rating. You can go the full power rating for a larger listening room. The efficiency afforded by the Kapellmeisters allows the opportunity to use a class A amplifier which can easily be designed for low powers such as these.

14 Window Helix Antenna

A low-cost and effective window-mount vertical antenna can be constructed from insulated hook-up wire and PVC (polyvinyl chloride) piping (Fig. 29). A 5- or 6-foot length of 1-inch PVC piping will do well. If you have a tall window you may be able to use a longer length with a secure attachment. A swivel mounting bracket which is attached to the window sill will permit you to tilt the vertical outward away from the window. When you do so be certain to use a guy arrangement at the top of the window (or even a long bracket) to prevent whipping in the wind.

Good performance on the 11- to 19-meter bands is obtained using a helical-wire length of approximately 15.5 feet which is laced through screw eyes turned into the PVC piping. Space the screw eyes to accommodate the overall length of

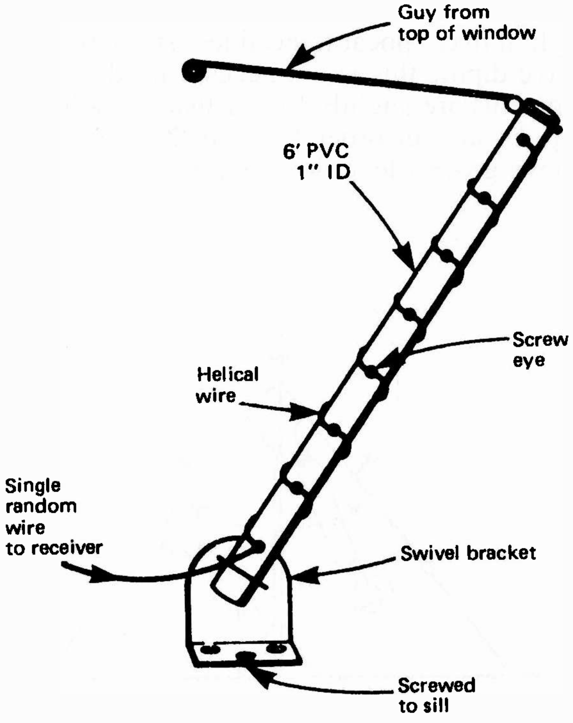

Fig. 29— Construction details for the Window Helix antenna.

wire you plan to use. In place of screw eyes, you may want to cement the wire to the pipe using the glue commonly used to cement PVC pipes together.

A 15.5-foot wire length also resulted in acceptable performance on the 22- to 31-meter bands as well. A random-wire feed was used permitting the position of the helical wire and the wire connecting from the base to the receiver to act as a long-wire so as to improve performance on the lower frequency shortwave bands. A tuner is helpful, though by no means mandatory.

Coaxial feed can also be used. When doing so, connect the outer braid to the swivel bracket.

If you live in an apartment complex where the management objects to window antennas, paint the pipe black so it will be less noticeable and attach a national flag to it. It would be un-American or un-Canadian to ask you to take it down, especially if you first raise the flag on a national holiday.

15 Inverted V Antenna

It may not appear so, but the Inverted V Antenna is really a modified version of the half-wave dipole. Looking at Fig. 30, it should be obvious how the Inverted V name is obtained and its relationship to the dipole antenna.

The Inverted V Antenna configuration has similar characteristics to a half-wave dipole and has the obvious advantage of needing only one mast or other central support. Although at first sight it may appear to need less space than a half-wave dipole this is not necessarily the case. The elements are slightly longer than for a half wave dipole, and in order to keep the elements well above ground level it is either necessary to have a tall mast (especially for an antennas cut for a low frequency band) or keep the angle between the elements quite large and have very long supporting lines. Angles of the Inverted V are typically 60 to 120 degrees. This type of antenna is probably most suitable for use in situations where suitable supports for the antennas are already available or are easily improvised. For example, antennas of this type are often installed over the pointed roof of a house (but must be kept reasonably well clear of the roof in order to obtain good results).

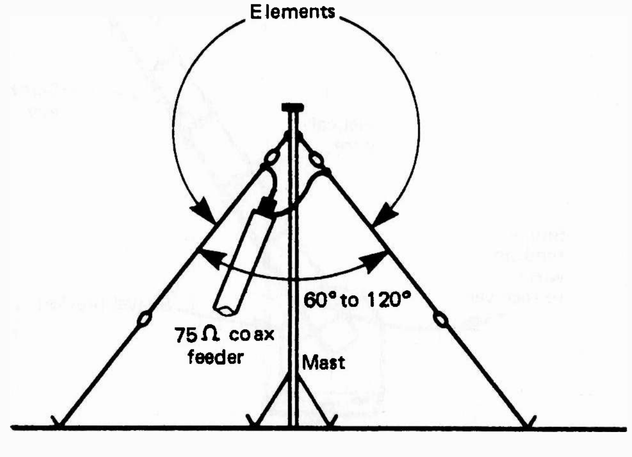

Fig. 30 —The arrangement used for the Inverted V Antenna. The length of one element of the "V" are given in the table.

The length of an Inverted V Antenna in feet is equal to 486 divided by the frequency in megahertz, or in meters it is equal to 148 divided by the frequency in megahertz. This is the total length of the two elements, and must be halved to give the length of each element.

The lists provided below give the element lengths (not the overall lengths) for Inverted V antennas for use on the shortwave, amateur and broadcast bands.

16 Audible Timer

This easy-to-build-timer circuit can be set for any period of minutes, from 1 minute to 7 minutes. A rotary switch is used to select the timing period.

The position to which the switch is set is indicated by numerals marked on the panel. A push-button resets the circuit and timing begins from the instant the button is released. At the end of the period there is a loud audible signal from the speaker. This is an intermittent note for maximum impact against a noisy background. The note continues for 1 minute. As well as the sound signal there is a high-intensity LED which comes on during the timing period and flashes when the period ends.

One of the advantages of this timer is that it can be set and run in the dark. This makes it suitable for dark-room timing. It is also ideal as a timer for use by blind or deaf persons.

How It Works. The Audible Timer relies on the principle of obtaining a relatively long timing period by dividing down the frequency of a high-frequency astable multivibrator. The chip used for the multivibrator is the well-known 555 timer in its CMOS form (Fig. 31). The frequency is independent of variations in the level of the supply voltage, so the circuit is ideal for battery operation. The preset resistor VR1 allows the frequency to be set to 273 Hz. This provides the alarm tone. The 273 Hz signal is divided by the 14-stage counter IC2. At pin 8 of the counter we obtain a signal at approximately 1 Hz which is used to make the note intermittent. The timing frequency comes from pin 14 of the IC, at which the astable frequency is divided by 2^{14}, or 16384, giving a frequency of 1/60 Hz, or 1 count per minute.

The output from pin 14 is inverted by transistor TR1 and fed to the clock input of a second counter IC3. This is a decade counter with decoded outputs. The outputs of this counter are normally at logical high, except that just one of the outputs is low at each stage of counting. When the counter is reset, output 0 goes high. On the next positive-going clock input, output 0 goes low and output 1 goes high. At each successive high-going clock input the outputs go high in turn from 0 to 7, repeating. The rotary switch S3 selects which of the outputs is to be used to indicate the termination of the timing period.

The circuit is reset by pressing button S2, which resets both counters and also the flip-flop formed by gates IC4a and IC4d. All outputs of IC2 go low. All outputs of IC3 go low, except for output 0, which goes high. Output 0 is not used in the circuit. A low output from one of the other pins of IC3 makes the output of the flip-flop (IC4 pin 3) go high. The output of IC4c goes low. This turns off the npn transistor TR2, which drives the loudspeaker, but turns on the pnp transistor TR3, causing the LED to light.

While the reset button is held, the output from IC2 pin 3 is low, turning off TR1. This means that the input to IC3 pin 14 is high. Counting begins when S2 is released. After 30 seconds, IC2 pin 3 goes high, and the input to IC3 goes low, but this has no effect on IC3. After 1 minute IC2 pin 3 goes low, and the input to IC3 goes high, causing

this counter to advance one count. Its output 1 goes high. The counter is incremented every minute until the output selected by S3 goes high.

The high level from the selected output sets the flip-flop. IC4 pin 3 goes low. This makes pin 9 low, allowing the signal reaching IC4c from IC4b to pass through to TR2 and TR3. This signal consists of the logical NOR of the astable signal (273 Hz) and the signal from output 8 of IC2 (1 Hz). The result is a note at 273 Hz, pulsing at the rate of 1 Hz. This is heard from the loudspeaker. The LED flashes on at the same time. Since the mark-space ratio of the astable output is high, the LED is turned on at almost full brightness during the on periods.

Construction. This circuit requires only a small current and is powered from a 9-volt transistor radio battery. Assuming that a small (1.5-in. diameter) loudspeaker is used, it can be housed in a small plastic case with the circuit. The parts can be assembled on a perf-board or some other pre-drilled board with holes on a 0.1-in grid. For stability of timing, and minimum effect of temperature, use metal-film resistors for R1 and R2 and a polystyrene capacitor for C1.

Assemble the astable circuit and the first counter (IC1 and IC2). Check that all outputs of IC2 go low when S2 is pressed. When S2 is released, a voltmeter shows that the output at pin 13 is approximately 1 Hz and that pin 3 changes from high to low or low to high every 30 seconds. Adjust VR1 to obtain this timing. While the remainder of the circuit is being built, it is convenient to use the output from IC2 pin 1 to drive TR1. The signal there runs at 1/15 Hz thus saving prolonged periods of waiting while testing the circuit.

Wire up TR1 and IC3, and test their operation, then complete and test the remainder of the circuit.

17 Long-Interval Alarm Timer

The Long-Interval Alarm Timer is capable of timing intervals of hours or even days. The maximum interval is two weeks. The timer sounds an alarm when the selected interval has elapsed. In addition, it sounds a different alarm if any attempt is made to turn it off before the end of the interval. In this way the unit can convey two messages: "Interval still in progress!", and "Interval finished!". While it is timing, the unit uses very little current (2.5 mA) so it is suitable for battery operation over prolonged periods.

The circuit was intended as a pill-box reminder, though it has other applications. If you have to take pills regularly, it is all too easy to forget exactly when the next dose is due. Conversely, it is easy to forget that a dose has been taken only recently and taking a second dose too soon could have undesirable effects, if nothing less than wasting money on expensive medicine.

The Long-Interval Alarm Timer can not prevent a person taking out too many pills when the pill-box is opened, neither can it make sure that the person actually swallows the pills removed, but, with intelligent use, it is a helpful personal prompter.

Pill Box. The circuit is housed in a small box serving as the pill-box. A micro-switch activated by the lid of the box lets the circuit know when the box is opened. The warnings are given by an audible sounder and by a pair of flashing LEDs. Shutting the box (presumably after having taken a pill) starts the long-period timer; both LEDs are out and there is no alarm sound. If the box is opened before the next time that a dose is due, an urgent high-pitched alarm sounds, bleeping rapidly, and the red LED flashes. This warns the person that it is not yet time for a pill. The person shuts the box, the sounder and LED cease their activity, and timing continues unaffected by the action of opening the box. When a dose is due, a slower, deeper bleeping note is heard and a green LED flashes. This continues until the box is opened.

The LEDs are of different shape, the red one

being triangular to reinforce the warning message. The difference of shape avoids the risk of confusion by color-blind persons.

How It Works. This project is based on the 7240 CMOS programmable timer chip (IC3), which has an accuracy of 0.5%. It contains a time-base generator, the frequency of which is decided by a resistor and capacitor (R3/VR1 and C2 in Fig. 32). The basic time period is RC seconds; so, given that the maximum value of R is 10 Megohms and the maximum value of C is 1000 -μF , the maximum time period is 10,000 seconds, or 2.8 hours. IC3 also has an 8-stage binary-divider chain. The total period available is 27 times the above, which is just over 14 days. But, as explained below, there may be practical problems in obtaining the very longest periods.

In Fig. 32, S1 is an optional power switch. S2

is the switch which is closed to initiate timing. In the pill-box application, this could be a microswitch, mounted so that it is closed when the lid of the pill-box is closed. Closing S2 generates a brief low pulse which goes to pin 11 of the timer IC3 and starts the timing. The output of the timer is normally high, but goes low for the whole of the timing interval. The length of the interval is selected by a rotary switch S3. If you have a dedicated version planned for the timer project, you could hard-wire the switch out of the circuit.

Pins 1 to 8 of IC3 are the outputs from the 8-stage divider chain. When the counter is reset they all go high, while timing they go through an inverted binary sequence. Thus pin 1 goes low after the basic time period, while pin 4, for example, goes low after 8 times the basic period. R5 connects the output to the reset terminal (pin 10) so that the counter is reset at the end of the interval. Figure 32 shows only 6 outputs being used; this is sufficient for the pill-box application, but there is no reason why all 8 outputs or any combination of fewer outputs should not be selected. For a single-period timer, omit S3 and wire the chosen output directly to the junction between R5 and R6.

The first stage of the logic consists of two NOR gates and a NAND gate wired as an inverter (part of IC1, 4001). These gates detect the two alarm states. Gate IC2a goes high (at pin 3) when S2 is open (box open) and the IC3 is timing (output low). This is the state of opening the box while the timing interval is in progress. Gate IC2b goes high (at pin 4) when S2 is closed and the output of IC3 is high. This is the state after the end of the interval if the box remains unopened.

A high output on either pin 8 or pin 9 causes a low output from Gate IC2c (pin 10). This makes the reset input of IC4 low. IC4 is a 14-stage counter with its own oscillator, which begins to oscillate when the reset is made low. The oscillator has a period of about 25 kHz, which is divided down to produce 1.6 kHz at pin 7 (high-pitched note), 200 Hz at pin 6 (low-pitched note), 6 Hz at pin 1 (fast bleeping), and 1.5 Hz at pin 3 (slow bleeping). The remainder of the logic consists of gates producing the fast high-pitched bleep signal, which goes to the red LED (D1) by way of transistor TR2, and the slower low-pitched bleep, which goes to the green LED (D2) by way of TR3. Both signals go to the speaker LS1 by way of TR1.

Putting It Together. The project is built on a board only 4 in. (10 cm) by 2.5 in. (6.5 cm). With a miniature loudspeaker, 1.5 in. (38 mm) in diameter, the unit is housed in a reasonably small plastic box. Since it requires only 2.5 mA, the timer runs for about a month on a set of four AA alkaline cells. There are only 3 logic gate ICs, IC1 (2-input NAND, 4011), IC2 (2-input NOR, 4001) and IC5 (3-input NAND, 4023) and all gates are used. The gates belonging to these three ICs are scattered in ones and twos all over the circuit diagram but can easily be identified by their symbols.

Begin with the trigger circuit IC1a/IC2d and timer 1C3, and their associated resistors and capacitors. For use as a pillbox timer, with a maximum interval of 8 hours (IC3, pin 8) values for the timing components are R3 = 3.3 Megohm, VR1 = 2.2 Megohm and C3 = 47 μF . Use a tantalum capacitor for C3. The tolerance of these is ±20%, but VR1 allows timing to be adjusted to accommodate this.

The main problem with tantalum and aluminum electrolytic capacitors is that they have an appreciable leakage current. The effect of this is that charging times tend to be longer than those calculated by multiplying R and C together. As a rule, tantalum capacitors have lower leakage than aluminum electrolytic capacitors. The most commonly available types have a leakage of 0.02 µA per volt per µF , with a minimum leakage of 1 µA. Low-leakage types are available with half this leakage, though such types are not widely stocked. The leakage quoted above is for a capacitor operating at its maximum working voltage; leakage is markedly reduced when operated at a lower voltage. The voltage across the capacitor in this project ranges from 1.6 to 4.2 volt, but the working voltage is likely to be 16 WVDC or even 20 WVDC for a 47-µF capacitor. This helps to keep leakage to an acceptable level. Using a 47-µF tantalum capacitor with resistances totaling 5 megohms or more is feasible. If really long intervals are required, make the resistor slightly less than the calculated value.

Having settled on a suitable value for R3, adjust VR1 until an interval of 225 seconds is obtained with S3 switched to the calibration position, position 1. This gives intervals of 8 hours, 4 hours, 2 hours , 1 hour and 30 minutes from pins 8 to 4. Other values of R3 and C3 may be substituted for other applications.

Next assemble the oscillator circuit, IC4 with resistors and capacitor. A voltmeter monitoring the output at pin 14 confirms that this works correctly when pin 12 is made low. Assemble the rest of the logic and check that the outputs at IC1 pins 4 and 10 and IC5 pin 10 behave as described earlier. Finally, add the transistor switches. TR2 and TR3 are shown in the schematic diagram as single NPN transistors, but the MPSA13 is a high-gain Darlington transistor. High-intensity LEDs are preferred but a red triangular one of normal intensity may be used for D1.

18 Twangy Distortion Unit

A conventional distortion unit has a major effect on the processed signal. Apart from adding distortion products, it also changes the input signal's envelope. In other words, it alters the way in which the volume of each note varies. Normally the output from a guitar-string pluck has a high initial level, but it rapidly falls away to a much lower level, and then decays at a more gradual rate. The envelope of a signal is the all-important parameter that governs its precise character and sound. In the case of a guitar it is the fast attack and quite rapid initial decay that gives the characteristic "twangy" guitar sound.

Clipping the signal from a guitar tends to give an output signal of uniform amplitude right up to the point where the input signal decays away to practically nothing. The fast attack of the input signal is retained, but the rapid fall in amplitude immediately after the attack period is not. This gives a sound which is largely twang free! Even with soft clipping, the amount of compression applied to the input signal is such that the original envelope of the signal is largely lost.

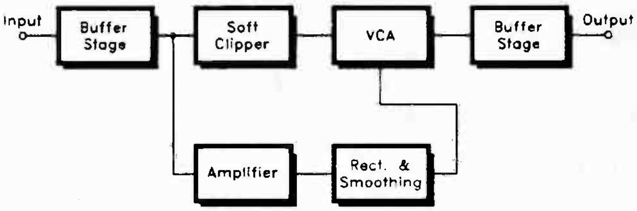

Fig. 33 —Block diagram for the Twangy Distortion Unit.

It is possible to produce a distortion unit that retains the original envelope of the input signal, or something close to it. It requires a rather more complex circuit than an ordinary distortion unit, but our Twangy Distortion Unit is reasonably

simple and inexpensive to build.

Signal Flow. The block diagram of Fig. 33 shows the arrangement used in the Twangy Distortion Unit. The input signal is applied to a buffer stage, and the signal is then split two ways. The main route is via a soft clipping amplifier, or a hard clipping amplifier can be used here if preferred. The distorted and compressed output signal from the clipping circuit is fed to a voltage-controlled amplifier (VCA), and then to the output via a buffer amplifier. The amplitude of the output signal is governed by the control voltage fed to the VCA. The higher the control voltage to the VCA, the higher the amplitude of the output signal. By feeding the VCA with a suitable control voltage, the output signal can be molded into the required envelope shape.

The control voltage is produced by a side chain which first amplifies the input signal from the buffer stage. The amplified signal is fed to a rectifier and smoothing circuit. This produces a DC output voltage that is roughly proportional to the amplitude of the input signal. Via the VCA, this DC voltage modulates the output signal to give an output envelope shape that is reasonably close to the envelope shape of the input signal. The output envelope is not identical to the input envelope because a few small errors occur in the amplitude control circuits. However, the match is close enough to give the required twangy sound.

The Circuit. Figure 34 shows the circuit for the input buffer and clipping amplifier stages. The circuit for the VCA and other stages is shown in Fig. 35. Taking Fig. 34 first, the clipping amplifier is based on chip IC1b. If hard distortion is required, simply replace D1 to D6 with a pair of 1N4148 silicon diodes, one diode for each string of three (D1-D3 and D4-D6) connected as in Fig.34; IC1a acts as the input buffer amplifier, and this is a simple non-inverting type which provides an input impedance of 50,000 ohms. IC1 is an NE5532N, which is a very low-noise dual operational amplifier.

A transconductance operational amplifier (IC2) is used as the basis of the VCA. Although this is a form of operational amplifier, apart from differential inputs it has little in common with ordinary operational amplifiers such as the 741C and LF351N. A transconductance amplifier is current rather than voltage operated. The output current is controlled by the differential input current. In practical circuits, including the present one, series resistors at the inputs plus a load resistor at the output effectively convert the device to a form of voltage operation. R10 is the resistor in series with the input signal, and R9 is the output load resistor. C4 plus R5 to R8 are used to provide biasing to the inputs of IC2, and they also provide a center-tap on the supply lines which is used as a sort of central ground bus for the output load resistor. Unlike ordinary, operational amplifiers, transconductance amplifiers are often used "open loop". IC2 is certainly used in this manner, and it therefore lacks any form of negative feedback circuit.

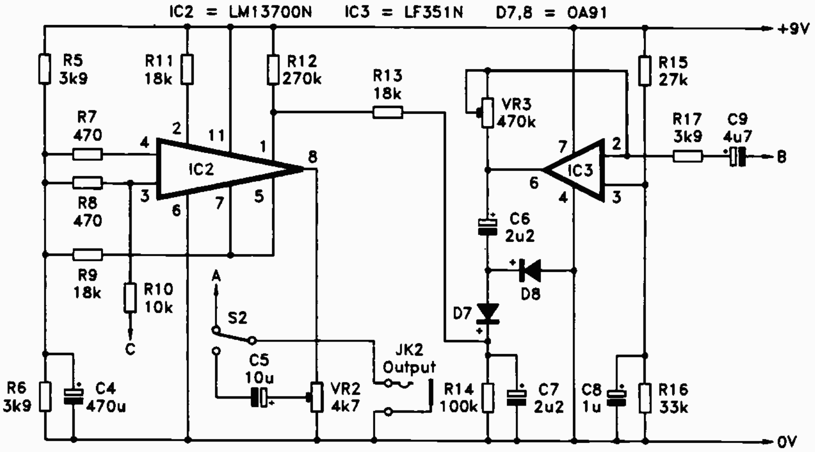

Fig. 35—The circuit for the voltage-controlled amplifier and rectifier stages of the Twangy Distortion Unit.

Chip IC2 has a built-in emitter-follower buffer stage which can be connected at the output of the transconductance amplifier. VR2 is the load resistor for this stage, and it also acts as a variable output attenuator. This enables the output level of

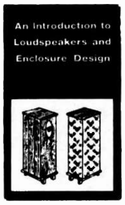
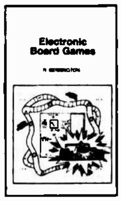
Book 1





☐ **BP84—Digital IC Projects $5.50** Presents simple and more advanced projects that help the reader develop a working knowledge of digital circuits. To help the newcomer to the hobby, the author has included a number of board layouts and wiring diagrams.

☐ **BP88—How to Use Opamps $5.95** A project builder designer's guide that covers operational amplifiers. Serving as both a source book of circuits and a reference book. The approach has been made as non-mathematical as possible and should be easily understandable by hobbyists.

☐ **BP98—Popular Electronic Circuits-Book $5.95** Designs for electronic enthusiasts who are capable of producing working projects from just a circuit diagram without the aid of detailed construction information. However, where relevant, any special procedures are described.

☐ **BP103—Multi-Circuit Board Projects $5.50** Contains information on the construction of 21 simple electronic projects, all of which may be constructed on the same specially designed printed circuit board. Many components may be used several times, reducing the cost of each project.

☐ **BP105—Aerial (Antenna) Projects $5.50** Your radio's performance ultimately depends on the antenna. This book covers practical antenna designs, including active, loop and ferrite antennas which perform well and are relatively simple and inexpensive to build.

☐ **BP106—Modern Opamp Projects $5.75** Construction projects that make use of many types of operational amplifiers available to hobbyists, including low-noise, low-distortion, ultra-high input impedance, low slew-rate and high-output current types.

☐ **BP107—30 Solderless Breadboard Projects $5.95** Each project is designed to be built on a "Verobloc" breadboard and presented with a brief circuit description, circuit diagram, component layout diagram, components list. Notes on construction and use are provided where necessary.

☐ **BP136—25 Simple Indoor and Window Antennas $5.50** Written for those people who live in apartments, have no garden or yard areas, or have other space-limiting restrictions that prevent them from constructing a conventional antenna system. The antennas have been designed, built and tested.

☐ **BP256—An Introduction To Loudspeakers and Enclosure Design $5.95** All you need to know about the theory and operation of loudspeakers and the cabinets that house them. Book includes the complete construction details of how to make an inexpensive, high-quality enclosure called the "Kapellmeister."

☐ **BP317—Practical Electronic Timing $6.95** Time measurement projects are among the most constructed gadgets by hobbyists. This book provides the theory and backs it with a wide range of practical construction projects. Each project has how-it-works theory and how to check it for correct operation.

☐ **BP350—Electronic Board Games $6.00** Here are twenty novel electronic board games that you can build. Whether you are interested in motor racing, searching for buried treasure on a desert island or for gold in Fort Knox, spinning the wheel of fortune, a musical quiz—there is something for you to build and enjoy!

☐ **BP368—Practical Electronics Musical Effecst Units $5.95** There is a constant clamor for musical effects projects by the hobbyist community. This book provides practical circuits for several projects that range in complexity and are sure to work. All the circuits are easy to build and use readily-available parts.

MILLIOHM
ADAPTER

MILLIOHM TESTER

Measure low resistances with this super simple circuit that connects to your DMM.

ROBERT A. HEIL

THE MILLIOHM ADAPTER ALLOWS resistances from 1 milliohm to 1 ohm to be measured with a high degree of accuracy on any digital multimeter. The circuit loads the device under test with a current of 100 milliamperes at 5 to 6 volts. The adapter connects to a DMM that is set on its millivolt- or 2-volt scale.

Ohm's law says that resistance equals voltage divided by current, or R = V/I. Thus, a DMM reading of 5.7 millivolts would correspond to 0.057 ohms. (5.7 mV/100 mA = 57 milliohms or .057 ohms.)

Circuit description

The milliohm adapter circuit, shown in Fig. 1, is powered from a 9-volt battery. A resistor to be tested (R_X) is connected across banana jacks J1 and J2, and a pair of banana plugs, connected directly to J1 and J2, plugs into the voltage input jacks of a DMM.

Switch S1 applies battery power to 7806 voltage regulator IC1. Capacitor C1 removes voltage transients. Resistors R1 and R2 form a voltage divider for the ground pin of IC1. Potentiometer R2 trims IC1's output voltage to exactly 6-volts DC. Potentiometer R3 sets the output current through R_X to 100 milliamperes. Because R3 is a relatively large resistance compared to R_X, the error introduced by different values of R_X (1 milliohm to 1 ohm), or the effect it will have on the 100-milliampere current source, is below 2%.

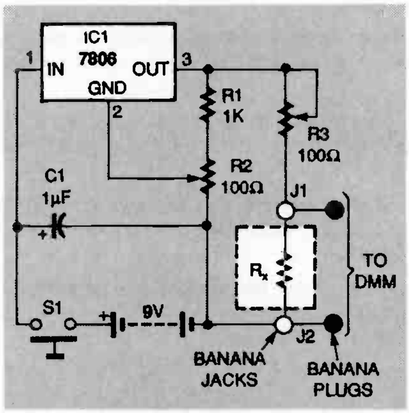

FIG. 1—MILLIOHM ADAPTER CIRCUIT. A resistor to be tested (R_X) is connected across banana jacks J1 and J2, and a pair of banana plugs, connected directly to J1 and J2, plugs into the voltage input jacks of a DMM.

Construction

A PC board is available from the source given in the Parts List, but the project is also easy to breadboard. You must select a case for the project before beginning the assembly. The prototype's case measures approximately 2 by 3¼ inches and is about 1 inch deep. The case has an aluminum cover.

A parts-placement diagram is shown in Fig. 2. Stuff the board as indicated, and check your work before continuing. Remove the covers from the banana plugs and place them into the common and the volt/ohms terminals of your DMM. Dab some petroleum jelly or other similar substance on the ends of the jacks protruding from the DMM. With the lid attached to the project case and facing up, press the upper left back of the plastic case onto the ends of the plugs stuck in the DMM. The petroleum jelly will transfer onto the project case and will mark the hole locations for drilling, allowing the adapter to plug directly into the DMM. Permanently mark those locations before continuing. Then turn the case over and similarly mark

the locations on the lid of the case for the two banana jacks directly above the holes for the plugs.

Drill appropriately sized holes in the case bottom and lid for the banana plugs and jacks. Be sure to use insulated jacks if your case has an aluminum nal plug covers. Next install the

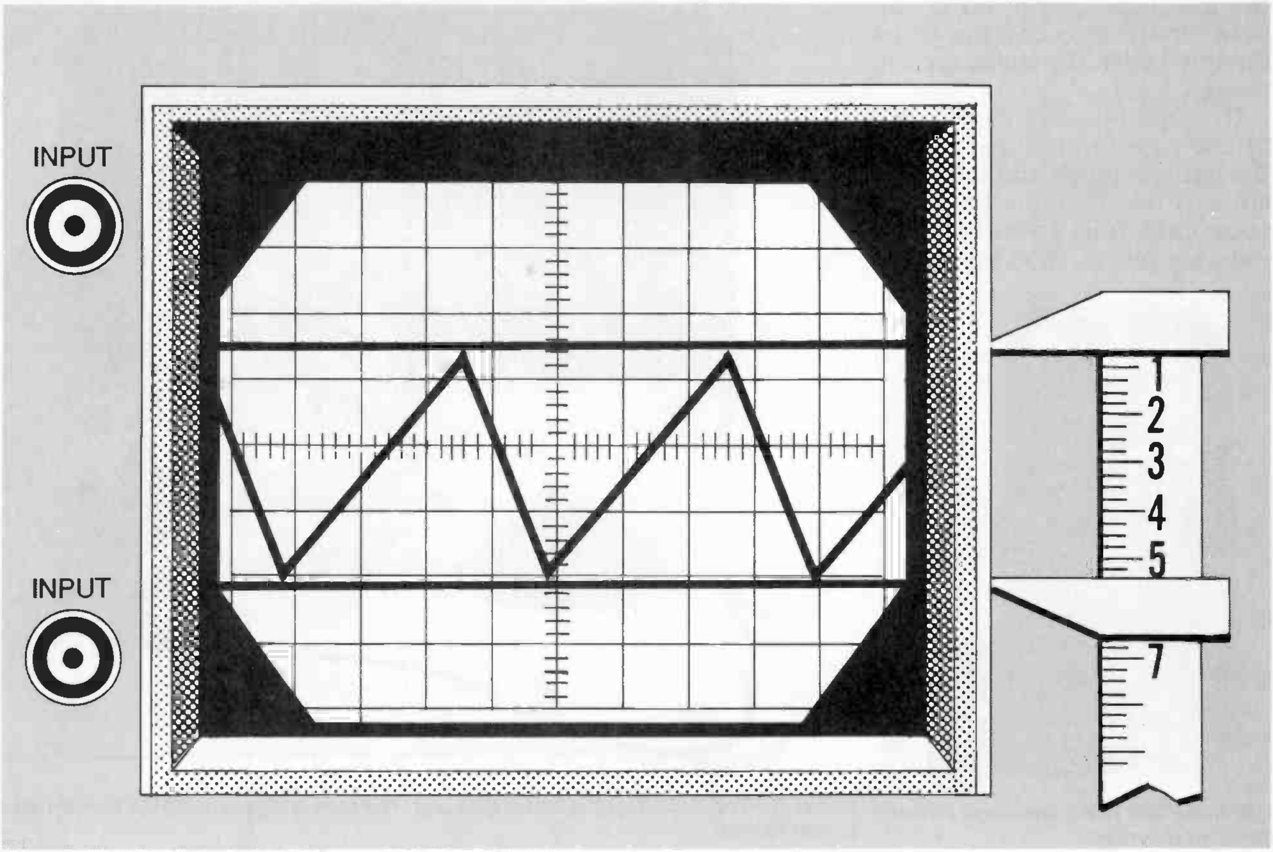
banana jacks in the case cover. Mount the PC board on the cover as close to the jacks as possible. You can secure it with No. 4-40 hardware on one corner with a plastic spacer.

Any momentary switch will work in the circuit, but make sure there's enough room in the case for the 9-volt battery. The battery connector can be made from an old 9-volt battery. Remove the old battery case and cut the leads from the cells to the connector at the top. Solder on new wires, and keep in mind that the small connector is now negative and the large one is positive.

Attach the negative side of the battery to the negative PC board input and the positive side to one side of the momentary switch. Solder another wire from the remaining side of the momentary switch to the positive PC board input. Solder one output from the PC board and one banana plug wire to a spade lug on the back of one banana jack. Do the same for the other jack. Figure 3 shows the inside of the completed unit.

Calibration

With the cover still off, plug the adapter into the DMM and set the range of the meter to 20 volts. Press S1 and adjust R2 for 6 volts DC. Next, place an ammeter across the banana jacks and adjust R3 for a reading of 100 milliamperes. To calibrate the circuit when used in conjunction with test leads, short circuit the leads together and write down the reading; then subtract that reading from any readings you take with the test leads. Now get out that junkbox and start testing those components with unknown values. Ω



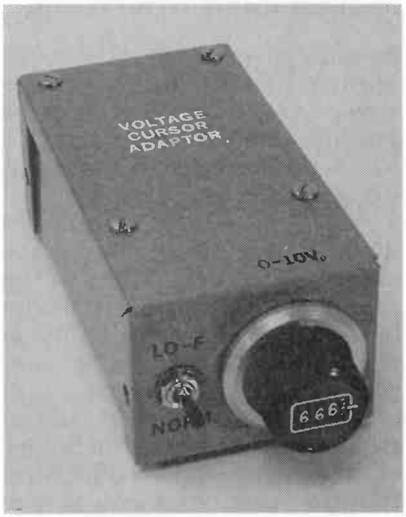
VOLTAGE CURSOR ADAPTER

Measure the voltage values of waveforms accurately and easily on your oscilloscope with the Voltage Cursor Adapter.

SKIP CAMPISI

HAVE YOU EVER HAD TROUBLE MEASURING the voltage value of a waveform on an oscilloscope screen? Are you tired of counting graticule squares and "guesstimating" those values? If so, you need the Voltage Cursor Adapter. It superimposes horizontal cursor lines on the top and bottom of the waveform—a kind of electronic calipers—to permit direct readout of the voltage value. The cursor lines extend across the entire screen.

The lower cursor (think of it as the floor) is the *zero-volt cursor* and the upper cursor (think of it as the ceiling) is the precision DC *reference voltage*. The cursors can be placed on any parts of the waveform that you want to measure, and the voltage can be read directly from a turns counter coupled to a precision potentiometer.



THE CURSOR ADAPTER superimposes horizontal cursor lines on the top and bottom of a waveform.

Figure 1 is the schematic diagram for the voltage cursor adaptor. The required 15 to 25-volt power to the circuit can be supplied either by batteries or a wall-mounted AC to 15-volt DC adapter. The author's prototype has a jack that will accept a plug from either the adapter or a battery pack consisting of two 9-volt batteries taped together.

The MC78L12 voltage regulator (IC1) supplies regulated 12-volts DC to the rest of the circuit. The ICM7555 timer (IC2), a CMOS version of the industry-standard 555, drives the CD4066B, a CMOS bilateral switch (IC3). This drive frequency can either be a normal frequency (NORM) of 100 Hz or a low-frequency (LO-F) of 10 kHz, depending on the setting of switch S1. Set S1 to LO-F for inputs below 500 Hz.

The DC reference voltage supplied to pin 3 of IC3 is set by R3, a 10-turn, 5000-ohm precision potentiometer. The voltage can be read directly from a turns counter dial coupled directly to the potentiometer's wiper. The accuracy of this reading can be 1% or better. Trimmer potentiometer R1 permits the voltage to R3 to be calibrated to precisely 10 volts.

The circuit is calibrated by setting the digital reading on the turns counter of R3 to the full clockwise position and adjusting R1 for a reading of 10 volts at the wiper of R3 with a digital voltmeter.

Bilateral switch IC3 converts the DC reference to a squarewave with exactly the same wiper amplitude. The squarewave output appears on the common pins 4, 9, and 10 of IC3 and coaxial plug PL1.

Building the adapter

The circuitry is simple enough to be built on an approximately 2 × 3-inch stock predrilled perforated board by point-to-point wiring methods. (The prototype circuit was built on a multipurpose board from Radio Shack.) There is nothing critical about component selection or placement. Figure 2 is a guide for positioning components on the circuit board.

The prototype was mounted in a two-part aluminum case that measured approximately 4 by 2 by 1⅝ inches. If you intend to put the circuit in similar project case, use the blank circuit board as a pattern and mark the hole locations on that part of the case with the ends folded up.

It is recommended that both

IC2 and IC3 be inserted in sockets. Insert and solder an 8-pin socket for IC2 and a 14-pin socket for IC3, as shown in Fig. 2. Insert and solder all other on-board leaded components in the positions shown, but do not trim any leads at this time.

Set the circuit board aside. Refer to Fig. 3, the mechanical assembly diagram, and drill the holes that you marked on the case half for mounting the ¾-inch standoffs. Then drill the holes for mounting jacks J1 and J2, precision potentiometer R3 with counter and switch S1 in the case end surfaces.

Mount the jacks, potentiometer and switch on the case half. Cut 3- to 4-inch lengths of No. 22 AWG stranded, insulated, hookup wires for making all connections to the board-mounted components, as shown in Fig. 2. Note: A lower cost counter can be substituted for the digital readout dial used in the author's prototype.

Solder one end of the wires from the jacks, potentiometer and switch and the other ends to the assigned terminal pads on the circuit board, leaving enough slack in the hookup wires to permit inverting the board and fastening it to the case half.

Carefully check all solder joints to be sure they are free of inadvertent bridges or cold soldering. Check IC1 to be sure that the three pins are identified and soldered correctly. Insert IC2 and IC3 in their sockets, observing the correct pin locations. After the Voltage Cursor Adapter is completely assembled it is ready for testing.

Connect the times 10 probe from the channel B input of your oscilloscope to the output plug (PL1) of the Voltage Cursor Adapter.

Measuring waveform voltage

Display the signal whose voltage you want to measure by plugging a lead from the signal source into the channel A vertical amplifier jack of your oscilloscope. Set the triggering on channel A. The output is variable from 0 to 10 volts.

Set your oscilloscope's attenuators to accommodate the 0 to 10-volt range. Using the CHOPPED/ALTERNATE mode, position in the zero cursor with the channel B vertical position control. Then adjust potentiometer R3 to position the *reference voltage cursor* at the correct level on the signal waveform you want to measure. Ω

MINI LOGIC ANALYZER

This mini analyzer is inexpensive, versatile, and easy to build.

JAMES J. BARBARELLO

AFTER YOU HAVE COMPLETED YOUR latest logic circuit design, you will probably want to build a prototype to test its operation. If the circuit is not complex, a common logic probe is all that's needed to troubleshoot it. However, if the circuit has multiple signals that must be checked for proper time phasing, or if it requires one or more complex driving signals to exercise its operation, then you need a more powerful testing tool.

Professionals use a logic analyzer and function generator to make these tests. Experimenters, hobbyists, and those on a tight budget will want to build the PC Mini Logic Analyzer. It costs only about $30 to build, but when it is linked to an IBM-compatible computer, it is sufficiently capable for most hobby applications. The PC Mini Logic Analyzer provides up to eight driving signals (outputs) and eight inputs. Each output can be programmed with up to a 64-bit pattern. In addition to its logic analyzer function, the unit can serve double duty as a digital integrated circuit (IC) tester.

The analyzer consists of a hardware interface with applications software. The interface buffers the signals that are sent from the computer's parallel port to the circuit to be tested. It also buffers the signals that are returned from the circuit to the computer, and shifts their voltage levels so that they are compatible with the PC's logic levels. The interface obtains its power from the circuit under test, so it will always recognize the proper logic levels: TTL at 5 volts, or CMOS from 3 to 15 volts. The interface can be connected directly to any parallel port on your PC.

The software displays 64 bits of the eight outputs and eight inputs simultaneously. It allows full on-screen programming of the outputs. Scan time (the time to process the 64 bits) can be adjusted from a high of about 100 bits/second on an average PC to a low of one bit every 10 seconds. The slower speeds allow you to single step through a circuit and observe how each output bit affects the prototype circuit's operation.

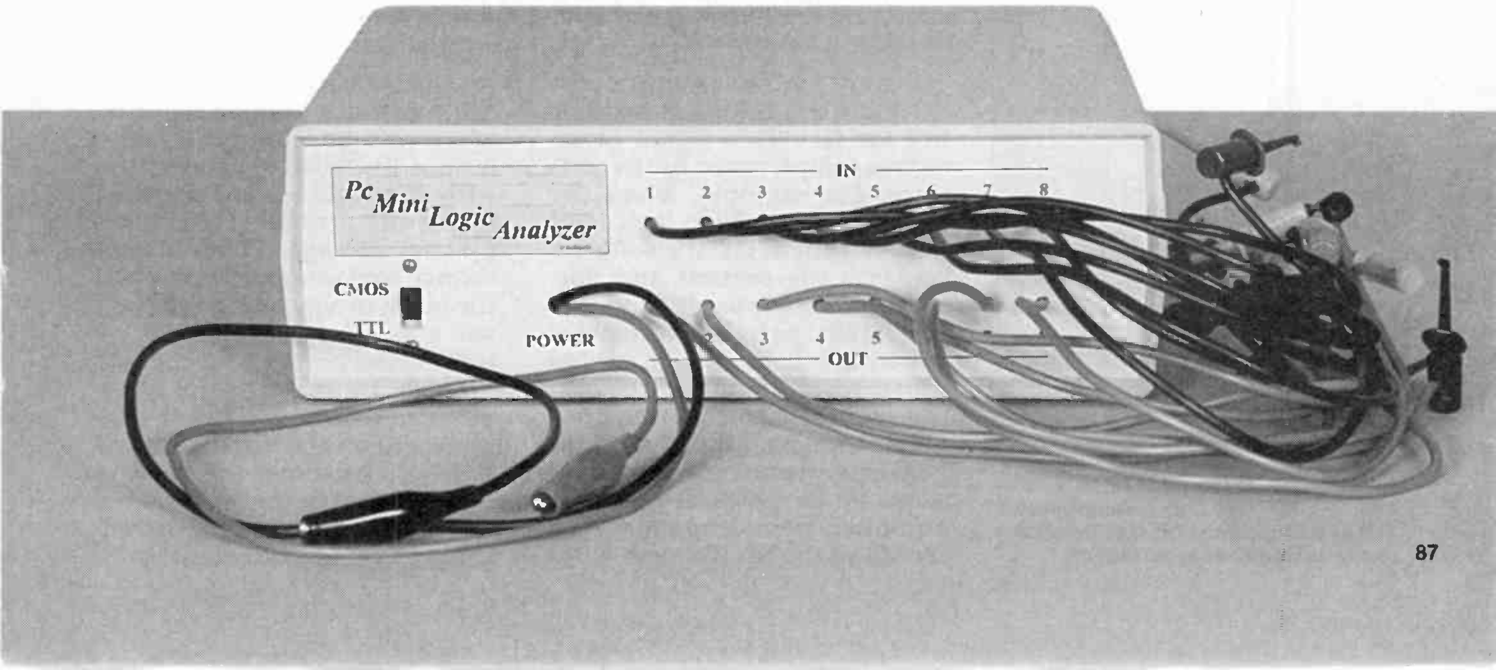
Best of all, the interface circuit is composed of common components, all available from most electronic component suppliers. Although a PC board layout is provided here, it is not essential for proper operation; the circuit can also be constructed on a solderless breadboard.

The hardware interface will be described first, followed by the software. Then, an actual logic analyzer application will be described, followed by an example of how to use the analyzer as a digital IC tester.

Theory of operation

The analyzer incorporates two basic functional blocks; a transistor buffer/inverter section, and an analog switch section that feeds voltage comparators. The transistor buffer/inverter section is shown in the schematic in Fig. 1.

Transistor Q1 in Fig. 1 is configured as a standard inverting switch. A signal greater than



about 0.7 volt from the parallel port (pin 2 for Q1) causes the transistor to conduct, raising the output (O1 for Q1) to about 0.3 volt. When a signal less than 0.7 volt is applied, the transistor does not conduct, and current is provided to any load connected to the output through the collector resistor (R2 for Q1). This signal inversion is compensated by the software. For example, when the user requests a high logic level to be output at O1, the software converts the request and outputs a low logic level at pin 2 of the parallel port. The transistor will invert that low logic level to a logic high, producing the output requested by the user.

FIG. 2—THE ANALOG SWITCH SECTION feeds the voltage comparators. Two of the analog switches in a CD4066B quad-analog switch IC (IC2-a and IC2-b) feed their outputs to the non-inverting input of IC1-d, one of the four voltage comparators in an LM339 quad comparator IC.

The transistor inverter/buffer performs two necessary functions. First, it acts as a current amplifier, providing more current than the parallel port could provide directly. Second, since the transistor obtains its operating voltage through D1, the output levels will be consistent with the logic levels generated by the circuitry that is supplied by that voltage. (The output voltage level is not dependent on the input driving voltage, which will always be that provided by the parallel port).

Diode D1 protects the interface against reverse power supply voltage. The approximately 0.3 volt lost across the diode is insignificant in the operation of the interface. The transistor inverter/buffer is used eight times

(Q1–Q8) to provide eight outputs.

The second functional block is shown in Fig. 2. Two of the analog switches in a CD4066B CMOS quad-analog switch IC (IC2-a and IC2-b) feed their outputs to the non-inverting input of IC1-d, one of the four voltage comparators in an LM339 quad comparator IC. When the control pin of an analog switch is pulled high, the switch will pass the input signal to its output, also putting from about 50 to 200 ohms in series in the process. When the control pin is brought low, the path between input and output becomes a very high impedance, effectively disconnecting the input from the output.

The signal from pin 1 of the parallel port is inverted twice, once by transistor Q9 and a second time by Q10. Therefore, the control signal for analog switch IC2-b is 180° out of phase with the signal for IC2-a. With a high signal at pin 1 of P1, switch IC2-a will be on, and IC2-b will be off. Conversely, with a low signal at pin 1 of P1, the switch IC2-a will be off, and IC2-b will be on. This allows the two switch outputs to be connected together (sometimes called a "wired OR"), because only one switch will be on at a time.

comparator's output goes high, and blocking diode D2 is reverse-biased. The high output at pin 14 of the parallel port pulls the parallel port pin 13 input high. A low signal from the comparator output allows the parallel port pin to sink voltage from pin 14 into the comparator's output through the diode. This pulls parallel port pin 13 low when a low signal is provided to the comparator. This arrangement allows signals greater than the 5-volt level of the parallel port to be processed. The analog switch/comparator block is used four times to accept eight inputs and provide them to the four comparators for input into the PC.

The reference voltages for the comparators are created in the voltage divider consisting of R25, R26, and R27. When switch S1 is in its TTL position, the voltage across R27 (provided to the comparators) will be about 2 volts with a 5-volt power supply. With S1 in its CMOS position, the voltage across R27 will be about 70% of the power supply voltage. Those voltage levels correspond to the lower limits of valid high logic levels for those logic families. A common ground reference is provided from the power supply through to the PC via the parallel port's pin 19 and clip 2.

Software

While a lot of software code is devoted to making a convenient interface for the user, the basic program flow is fairly simple (see the flowchart in Fig. 3). First, the address of the parallel port is identified and called ad0. Since the parallel port must be addressed with three sequential addresses, the two addresses that follow are defined as ad1 (ad0 + 1) and ad2 (ad0 + 2). Because the analyzer has 16 lines, each with a 64-bit sequence, an integer array is set up to hold each bit's value for each line. The array has maximum dimensions of 16 by 64, or a(16,64). Other necessary variables are also set up at this time. Pin 14 is also brought high to serve as the pull-up voltage for the parallel port inputs.

Next, a counter to loop between 1 and 64 is set up. The software then makes sure the desired output pattern(s) are defined, and if they aren't, it defines them. The desired patterns are inverted (to compensate for the hardware inversion in the interface transistors) and stored in the integer array. Next,

the bit counter is incremented and the next bit is sent out to the parallel port. The status of the port is then read and the results are displayed. The software then loops back to the bit counter, and the input/output process continues. There is more to the actual program code, but the basic analyzer operation is captured in just those few steps.

Construction

The circuit layout is not critical, so you can use either the PC board and parts-placement diagram shown in Fig. 4, or follow the schematic diagram and build the circuit on an experimenter's breadboard. For either assembly method, IC sockets are recommended.

Once the circuit is constructed, and before you begin the final wiring, decide on the case style (if any) for enclosing the analyzer. Because 16 wires and test clips extend from the circuit board, it is wise to choose a wire-coding arrangement that will help you easily recognize each input and output lead.

Use No. 20 stranded hookup wire for the 16 input/output leads, connecting one end to the 16 points identified as O1–O8 and I1–I8. Again using No. 20 stranded wire, connect a red lead to Clip 1 and a black lead to Clip 2, and also connect switch S1.

Decide if you want to have the parallel port cable connected to the board directly, or if you want to add a DB-25 connector. For the integral cable option, obtain 15 four-foot lengths of No. 22 or 24 stranded wire, or a four-foot length of 15-conductor cable. Then use those leads to connect the appropriate points from the circuit board to the pins of a male DB-25 plug. If you use a connector, make the appropriate connections from the circuit board to a female DB-25 socket mounted on the back of the case with wire cut to the size of the enclosure.

The last step is to attach connection devices to the 16 input/output lines and power leads. Use micro-clips for the 16 input/output lines, and insulated mini alligator clips for the power and ground leads. Route the wires through holes in the enclosure and attach the connectors. Complete the assembly

by mounting the circuit board in the enclosure and mounting S1. Figure 5 shows the author's prototype unit.

Checkout

To test the analyzer, you'll need a 9-volt battery, a voltmeter, and a few jumpers. First make sure that there is no continuity between the board and the eight output leads O1–O8. Then connect the power terminals to the 9-volt battery (red to +, black to −). The voltage between each of the output leads and ground should be the battery voltage less the voltage drop across diode D1. For example, if your battery terminal voltage is 8.9 volts, the voltage at O1 should be about 8.6 volts. The actual voltage is not critical, because the drop across D1 and the individual transistors will vary slightly depending on the actual devices installed.

Next, connect O1 to P1 pin 3; O2 should now read between 0 and about 0.5 volt. Connect O1 to P1 pins 4 through 9 in turn, reading the outputs (O3 through O8 respectively). Finally, connect O2 to P1 pin 2 and read the output at O1. This entire procedure is summarized in Table 1.

To check the interface input circuits and parallel port connections, use the program MATEST.BAS shown in Listing 1. (All of the software for this analyzer project will be made available on the Gernsback BBS, 516-293-2283, v.32, v.42bis, as a file called MINI-ANAL.ZIP.) Extract the program MATEST.EXE from the zipped file or type it in by hand and run it from QBasic. Connect each numbered output to its corresponding input (O1 to I1, O2 to I2, etc.). Connect the power leads to a 9-volt battery, and connect the analyzer output to your computer's parallel port. Place S1 in the CMOS position.

The program will use the outputs to create a logic 1 and then logic 0 for each of the eight inputs. It will read the inputs to determine if they were processed correctly. When you execute the program, it will ask you for the parallel port address.

Press ENTER if you're using LPT1 at the standard address of 888. Otherwise, type in the decimal address of the parallel port and press ENTER. The program will then test all inputs and outputs, and give you the results. You will either get a message "Interface Tests OK," or one or more messages indicating which inputs or outputs did not perform as they should.

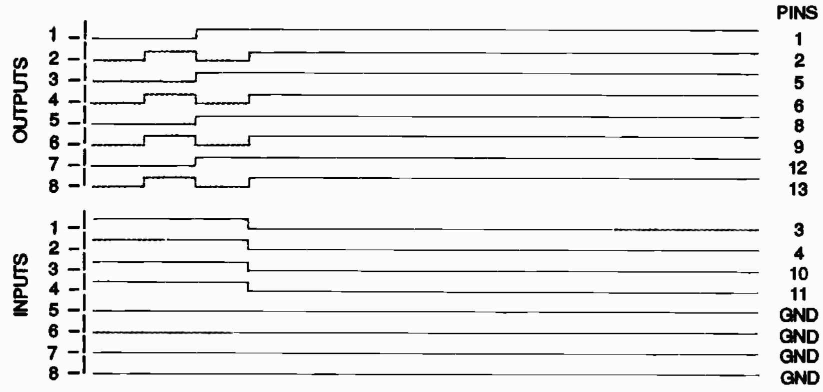

FIG. 14—THE TRUTH TABLE of the CD4011B is implemented in this bit pattern.

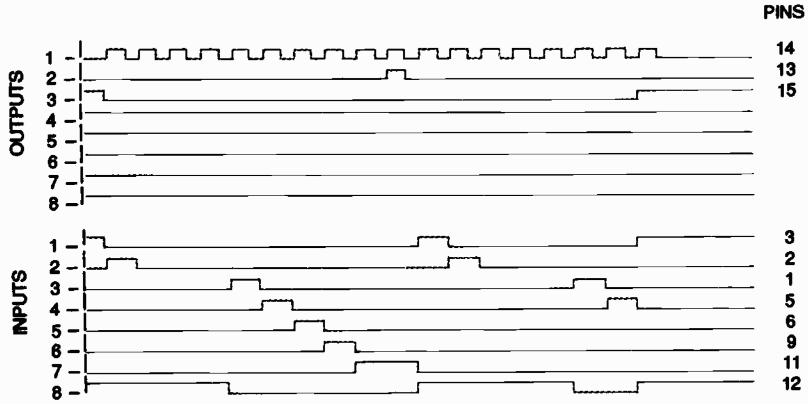

FIG. 15—BIT SCAN for the CD4017B CMOS decade counter/divider.

Logic analyzer

To use the unit as a logic analyzer, begin with the following sample problem: Assume Fig. 6 is a self-clocking circuit that you designed to provide a squarewave output that is one quarter of the input frequency. The clock can be disabled with an external switch, and the LED should turn on with the rising edge of the clock. If wired as shown, the circuit does not operate properly. Most notably, the LED doesn't flash.

Before testing the circuit, IC3, a simple squarewave generator, must be replaced with one of the analyzer's outputs. If IC3 were left in the circuit, there would be no way to synchronize it with the analyzer, and the display would drift, resembling an oscilloscope trace without proper sync. The IC3 oscillator is therefore simulated by programming an analyzer output to produce a squarewave.

Although IC1 is a divide-by-ten counter, the analyzer has a 64-bit pattern that is not evenly divisible by ten. Again to avoid pattern drifting, a second output must be programmed to reset IC1 after ten clock pulses.

Finally, the correct monitoring points must be determined. For the best understanding of circuit operation, all possible points (A through H) should be monitored. The resulting test circuit is shown in Fig. 7.

The bit pattern obtained is shown in Fig. 8. The fault with the circuit was that the LED would not light. The problem is verified in the bit pattern showing that inputs I7 and I8 are not switching. However, the outputs of IC1 are performing as expected, and the outputs of the first two NOR gates (I5 and I6) are also valid. Re-examining the circuit with the help of the analyzer reveals the fault: At least one of the inputs (I5 and I6) to the third NOR gate (I7) is always logic high. That makes the output always logic low. The circuit really needs a NAND function to produce a low logic level when the two inputs are high, and to produce a high logic level at other times. The solution is to change the circuit to incorporate a NAND gate. The revised circuit is shown in Fig. 9, and the resultant bit pattern is shown in Fig. 10.

Replacing the NOR gate with a NAND gate has provided the desired signals at I7 and I8. (The fourth NOR gate was also replaced with a NAND gate arbitrarily—either gate can serve as an effective inverter/current sink for the LED). By looking at the new bit pattern, you might notice another problem. The circuit is dividing by four, but it is not producing a symmetrical squarewave. The pattern is symmetrical through the eighth positive clock pulse (O1), but then stays low for the remaining two clock pulses. In viewing the bit pattern this will be immediately obvious, and it is much better than attempting to watch the LED while determining what's wrong.

FOIL PATTERN FOR THE MINI ANALYZER.

A look at the I7 and I8 waveforms shows how to solve the problem. They would both be symmetrical if they ended after the eighth clock pulse. This can be accomplished by routing the ninth output of IC1 (called output 8 because the first one is called output 0) to the reset pin. This will create a divide-by-8 counter instead of a divide-by-10, and it will generate the bit pattern in Fig. 11. Notice that the O2 reset pulse has been removed—it is no longer needed because a hardware reset has been incorporated. Because the circuit divides by 8, and the 64-bit pattern is divisible by 8, the bit pattern is stable, or synchronized. The final circuit configuration is shown in Fig. 12. It meets all of the original requirements in that the output is the input divided by 4, it is symmetrical, and the LED lights on the rising edge of the clock.

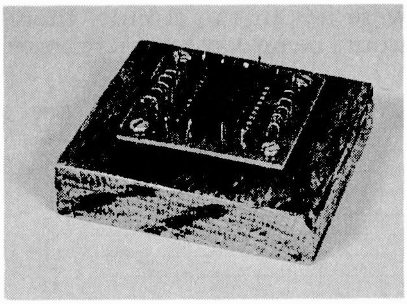

FIG. 16—THIS SIMPLE JIG makes connections to the IC pins easy.

IC checker

This example will expand on the last example. The analyzer will check for proper operation of the CD4011B NAND gate. Begin with the truth table and functional diagram of the 4011 shown in Fig. 13. Any combination of inputs other than both logic high will produce a "1" output; a logic high to both inputs of any of the four NAND gates will cause that gate to produce a "0" output. To test the IC, you must program the four possible input bit patterns for each gate and view the corresponding outputs. If each gate stays high except when both inputs are high, the IC is functioning properly.

The truth table is implemented in the bit pattern of Fig. 14. Note that the pin connections are indicated to the right of the traces. Inputs 5 through 8 are grounded to avoid stray pickup. Ground any unused inputs to avoid stray signal pickup through the high off-impedance inputs of the CD4066 switches. Alternatley, you can attach a pull-down (terminating) resistor to each input. Any resistor value of 10,000 ohms or more will work fine and not load the source circuitry.

Instead of a single bit, a group of bits (five in this case) will be used for each state. Each set of inputs to the 4011 (O1 and O2, O3 and O4, O5 and O6, and O7 and O8) have the same pattern. The first five bits of each set are low. Then the second five bits are low on the first input and high on the second. Then the pattern flips, with the next five bits high on the first input and low on the second. Finally, the bit pattern shifts to both inputs high. In each instance, the expected IC output pattern (I1, I2, I3 and I4) show a high input until the inputs shift to both high. Then the IC output goes low.

A bit scan for the CD4017B CMOS decade counter/divider is shown in Fig. 15. The input bit pattern from a reference book was used directly, except that IC outputs 2, 3, and 4 were not sensed (because the IC has 11 outputs, and the analyzer has

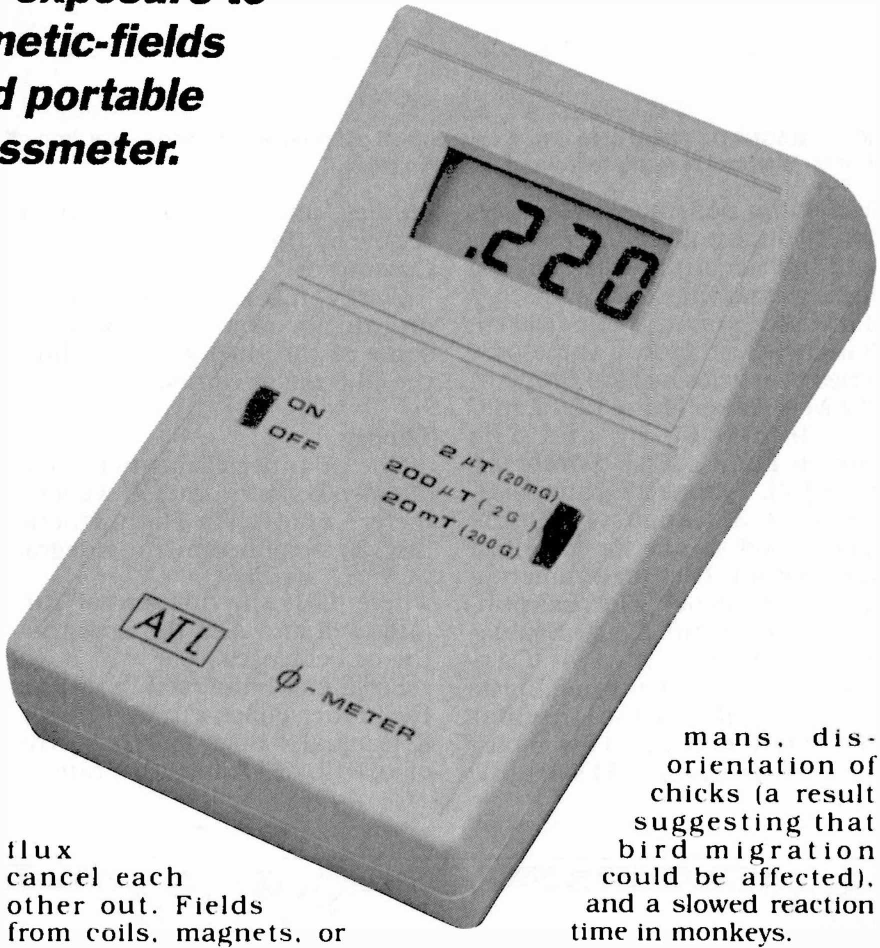
MAGNETIC FIELD METER

Determine your exposure to line-frequency magnetic-fields with our easy-to-build portable ELF gaussmeter.

REINHARD METZ



IF YOU ARE ONE IN A GROWING number of people who are concerned about the potentially harmful effects of exposure to magnetic fields, you will be interested in this important construction project. Now you can build your own gaussmeter, and determine the magnitude of magnetic flux densities in and around your home. Our hand-held, battery-operated magnetic-field meter is sensitive from 0.1 microtesla (µT) to 20 milliteslas (mT), and has a frequency range from 50 Hz to 20 kHz.

Why all the worry?

Magnetic fields are all around us. They occurr from the generation, distribution, and use of 50 and 60-Hz electricity, electronic equipment, and even from Earth's magnetic field, which has always been present throughout Man's evolution. Man has been "tuned" into Earth's steady magnetic field of about 30 µT (at sea level) for millions of years. Some sources of excessive magnetic fields that have caused the greatest public concern include power-distribution substations, power lines, CRT terminals, and use of appliances.

Magnetic field intensities can vary greatly, depending on the exposure source and the distance from that source. The rate at which the field intensity falls off with distance can vary from one source to another, depending on how well the current-carrying lines are balanced, or how well the opposing lines of magnetic flux cancel each other out. Fields from coils, magnets, or transformers drop off rapidly with distance by a factor of $1/r^3$. In power lines, if currents flow in opposite directions, the drop-off is $1/r^2$ because of partial field canceling. When unbalanced current exists, the field intensity falls off less rapidly as $1/r$.

Figure 1-*a*, -*b*, and -*c* show drop-off rates of $1/r$, $1/r^2$, and $1/r^3$, respectively. Figure 2 lists some of the many sources of magnetic field exposure, with their range of intensities and drop-off rates.

Although a great deal of controversy still prevails, many people in the scientific community believe that exposure to magnetic fields of extremely-low frequency (ELF fields of 1–100 Hz) may pose a risk to human health. Some disturbing findings of exposure to ELF fields include a significant increase in serum triglycerides (a possible stress indicator) in humans, disorientation of chicks (a result suggesting that bird migration could be affected), and a slowed reaction time in monkeys.

A study conducted by epidemiologist Nancy Wertheimer and physicist Ed Leeper, found that exposures to magnetic fields as small as 0.25 µT correlated with a rise in cancer rates. In the study, the researchers examined wiring and transformers in the neighborhood of birth homes of children who had died of leukemia between 1950 and 1975, along with those of a control group of children who did not have the disease. The results of their studies were published in *The American Journal of Epidemiology* (March, 1979). Some experts argue that other factors, such as pollution and exposure to chemical carcinogens, make interpretation of those findings very difficult.

Standards for acceptable exposure to ELF fields are emerging, as are results of studies

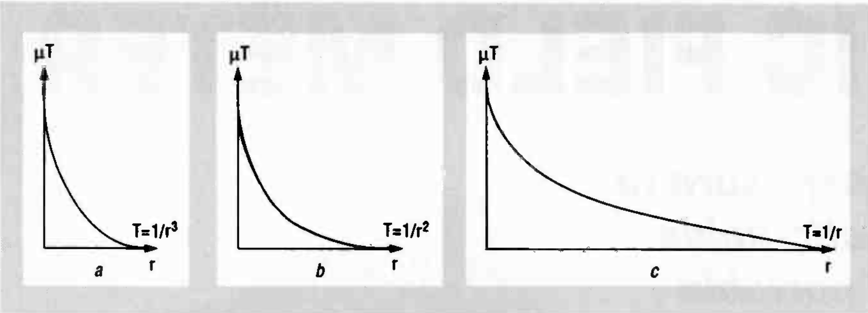


FIG. 1—MAGNETIC FIELD drop-offs. A fast drop-off of $1/r^3$ (*a*), $1/r^2$ (*b*), and a slow drop-off of $1/r$ (*c*) is typical of many sources of magnetic fields.

describing possible hazard levels. If you are more interested a detailed account of scientific findings and the political history of the effects of magnetic-field radiation, we suggest a three-part series of articles by Paul Brodeur, *The New Yorker* (June 12, 19, and 26, 1989). "60-Hz and The Human Body", *IEEE Spectrum*, Parts 1–3, Volume 27, Number 9, pages 22–35 (August, 1990) is also a good source for technical information. The Environmental Protection Agency (EPA) has published a report titled "The Evaluation of the Potential Carcinogenicity of Electromagnetic Fields", publication number EPA/600/6-90/005B. This report contains analyses of 64 scientific studies, and is currently under review by the Scientific Advisory Committee.

Well, that's enough background for now. Let's examine some of the theory behind how the ELF meter works.

Theory

The quantity of magnetic flux density, **B**, is in units of webers/meter², or tesla (T). The magnetic flux, ϕ, is defined by the integral

$$\phi = \int \mathbf{B} \cdot d\mathbf{s} = B \times A$$

where **ds** is the differential surface area and A is the area that the coil encloses.

For a coil immersed in a field, the induced open-circuit voltage, E, is equal to the number of turns of a coil, N, times the rate of change of flux through it.

$$E = |N \times d\phi/dt|$$

Note that the value of $N \times d\phi/dt$ is actually negative with respect to the induced voltage value, but for our purposes we will just consider the magnitude of the product. The direction of the induced current is such that its own magnetic field opposes the changes in flux responsible for producing it.

If we substitute for ϕ we get

$$E = N \times A(d\mathbf{B}/dt)$$

If the magnetic field of a sine wave is $\mathbf{B} = a(\sin \omega t)$, a is the amplitude in teslas and ω is the angular velocity ($2\pi f$), then

$$d\mathbf{B} = a\omega(\cos \omega t)dt, \text{ and}$$

$$E = N \times Aa\omega(\cos \omega t)$$

Since $\cos \omega t$ varies from +1 to −1, the peak magnetic field is defined as

$$E = NAa\,\omega$$

For a frequency of 60 Hz, ω equals

$$2\pi \times 60 = 377$$

For a coil size of 3½" × 3", the area is .0068 m², and therefore

$$E = 2.56\ N \times a$$

For the 12-turn pickup coil that we'll use, the sensitivity is 30 µV per µT.

circuit board. For remote sensing, an external field coil probe can be used. Figure 3 shows the complete schematic of the circuit. The magnetic field picked up by the coil appears as a voltage, which is proportional to field strength and frequency at the input of a cascaded amplifier IC3-a, -b, and -c. With a first stage amplifier gain of 3.3 set by R12-R10, the overall sensitivity is 100 μV per μT, or 100 mV per mT. The meter sensitivity is nominally 2 volts full scale, leading to the lowest level sensitivity of 20 mT full scale.

Op-amp IC3-a amplifies the signal to a normalized level of 100 μV per 1 μT. That voltage is further amplified by 1, 100, or 10,000 by IC3-b and -c. The three amplifier stages provide the three magnetic field ranges of 2 mT, 200 μT, and 2 uT (full scale). Components R3-C3 and R12-C7 establish a frequency roll-off characteristic that compensates for the frequency-proportional sensitivity of the pickup coil, and set the 20-kHz cut-off point.

Finally, IC3-d is a precision rectifier and peak detector. Its output drives IC1, a combination analog-to-digital (A/D) converter and LCD driver. Components R25–R29 and C13–C17 are used by IC1 to set display-update times, clock generation, and reference voltages. The decimal points are driven by IC2, as determined by the range-select switch S2. Transistors Q1 and Q2 serve as a low-battery detector, and turn on the battery annunciator in the LCD when the battery voltage drops below 7 volts.

Assembly and checkout

The finished unit shown in Fig. 4 uses a double-sided PC board, which is available from the source mentioned in the parts list. We also show the component side and solder side of the PC board if you choose to make it yourself. You can, however, build the circuit on a perforated construction board if you like, but remember to include the 18-turn remote sensing coil, L1, as indicated in the Parts List. Mount all parts below the LCD display first. It's easier to fix assembly problems if a socket is used with the LCD. Install all parts as shown in Fig. 5 paying attention to component valves and capacitor polarities. If you are using the internal sensing coil, install jumpers between L1-TP3 and L1-TP4.

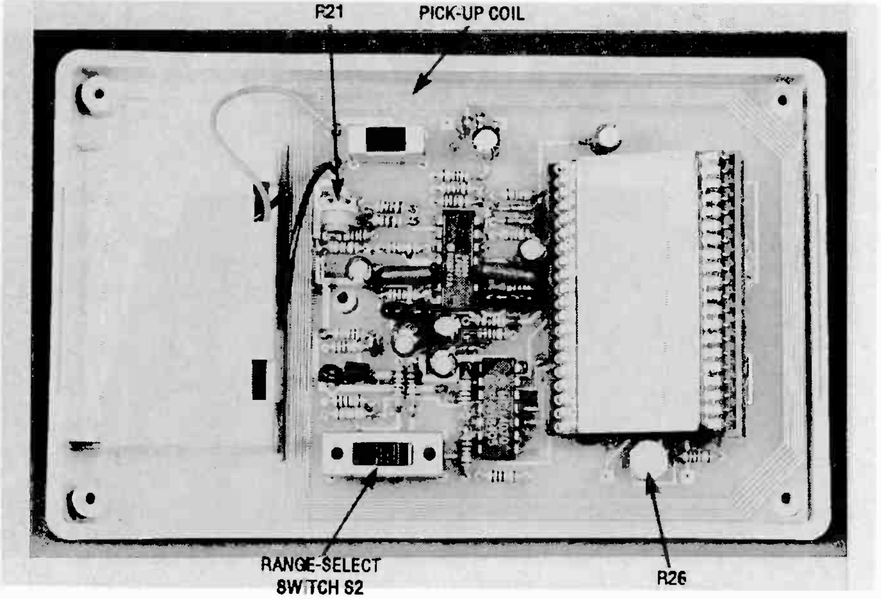

FIG. 4—THIS IS AN INTERNAL VIEW of the magnetic field meter. Assembly is easy, just install all components below the LCD first.

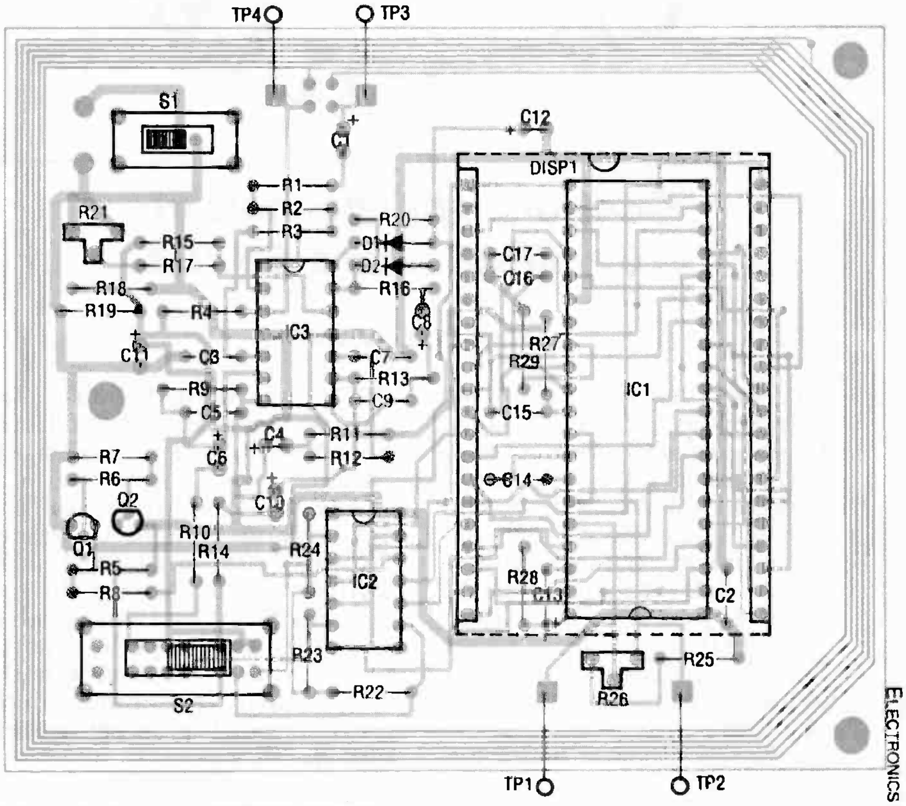

FIG. 5—PARTS PLACEMENT DIAGRAM.

If you are using the case specified in the parts list, raise and angle the display as necessary with wire-wrap IC sockets. Make holes in the front panel for S1 and S2. Mount the finished PC board in the case using a spacer for the single screw holding the center bottom of the board, and attach the battery connector.

With power on, adjust R26 for 1.000 volt between TP1 and TP2. Then, select the 20 mT range and short the pickup coil with a very

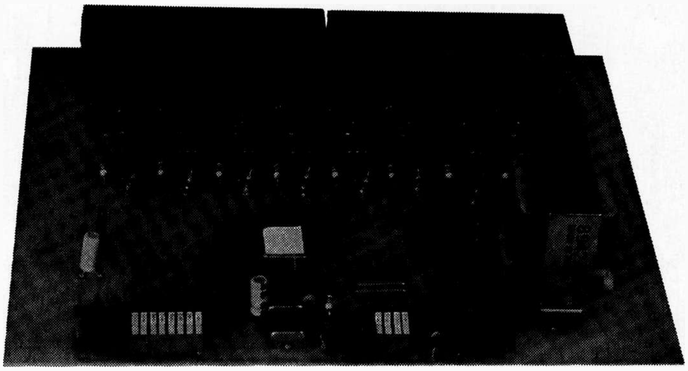
POWER CONTROLLER



Control eight channels of 120-volt AC with a 68705.

RICHARD L. ROANE

HAVE YOU EVER WANTED TO VARY the power delivered to a 120-volt AC load under software control? In this project a 68705 microcontroller will do just that. Specifically, it can control eight discrete power Triacs, each of which delivers power in 32 smoothly graduated steps ranging from 0 to 97% of full power. The value delivered to one channel is independent of the value delivered to any other channel. Loads can include light displays, universal motors, heaters, and other appliances.

In this circuit, the power level is set by software, not a potentiometer. The software includes a basic set of routines for processing interrupts and setting the power level. The software also includes five test and demonstration routines for putting the circuit through its paces. Moreover, there's plenty of room to add your own routines to the 68705's built-in EPROM. An easy-to-build single-sided circuit board makes assembly easy.

The basic circuit is simple, yet versatile enough to accept inputs from on-board DIP switches; alternatively, the inputs can be driven from a microcomputer bus or parallel port, or a stand-alone device with TTL-compatible outputs. There are 12 input bits to set modes and specify values.

Circuit design

The circuit, shown in Fig. 1, consists of a power supply, AC line synchronizer, Triac output control, input circuitry, and support devices.

The power supply is a conventional 5-volt circuit built around a 7805 regulator (IC3) and several other components (transformer T1, bridge BR1, and C1–C4). The AC line synchronizer consists of an optocoupler (IC2), a current-limiting resistor (R1), and a bias resistor (R2). The power controller generates variable power levels with phase-control techniques. When using a Triac to control a load, the power delivered can be varied by triggering the Triac after the start of an AC half-cycle.

For example, by triggering the Triac shortly after the start of a half-cycle, the load will receive almost full power. Triggering in the middle of a half-cycle will supply the load with half power and triggering close to the end of a half-cycle will result in the load receiving little power.

In this project the controller is synchronized to AC power-line zero crossings, which occur at a rate of 120 times per second. The microprocessor's internal timer then divides the interval between crossings into 32 steps, thus delivering gradually increasing amounts of power to the load.

The output of the optocoupler is a negative-going pulse that drives the microcontroller's interrupt input directly at a rate of 120 hertz. Each time IC1 receives an interrupt, it recalculates the time to generate Triac trigger pulses on Port B of IC1.

Each bit of Port B is connected to a Triac control circuit; since they're all identical, only Port 7 will be described in detail. Port B7 of IC1 drives transistor Q1 via resistor R4. (Q1 is required because the 68705 can't sink enough current to trigger Triac-driver IC4 directly.)

When it's time to turn on Triac TR1, the microcontroller delivers a 10-microsecond negative-going pulse to port PB7. That pulse briefly enables the transistor, which causes current flow through the LED inside IC4. Although a Motorola MCP3011 Triac driver was used in this design, any similar device could be used, as long as it doesn't have an internal zero-crossing detector. That type of driver allows only two modes of operation: full on and full off.

The Triac driver's LED then triggers the photon-coupled Triac within the IC, which in turn triggers TR1 and delivers power to the external load. Resistor R5 provides current limiting for IC4, and R6 and C7 form a snubber network to filter line transients that could cause the Triac to trigger falsely.

The hot side of the power line connects to the MT1 terminal of all the power Triacs (TR1–TR8). The specified Triacs are rated for 4 amperes at 200 volts. They are isolated-tab versions, and were selected because heatsinking is mandatory. With the specified Triacs, the maximum load is 100 watts per output. Larger loads can be handled by substituting Triacs with higher current ratings. Be sure to use proper heatsink and isolation techniques.

Input circuit

The input circuit consists of Ports A and C of the microcontroller, along with two banks each of DIP switches (S1 and S2), SIP resistors (RN1 and RN2), four sets of 0.1 inch header jumpers (P1–P4) for mode selection, a 14-pin header (P5) connected to Port A, and a four-pin header (P6) for input selection.

The P1–P4 jumpers allow both the common resistor legs and the common switch poles to be tied to either ground or +5-volts DC, or to be disconnected from the circuit entirely. If programmed as inputs, the ports should not be left floating because this might cause erratic operation. Connector P6 allows an external device (e.g., a computer) to drive the controller's inputs.

The 68705P3 requires a few support components. Crystal XTAL1 runs at a frequency of 3.58 megahertz, which should not be altered. Capacitor C5 loads the oscillator to keep it at the correct frequency, and capacitor C6 keeps the reset pin low for an instant, thereby giving the 68705 time to stabilize after power up. Momentary switch S3 provides for resetting the circuit. Although unused in the prototype, an external connection is provided to the microcontroller's RESET input, which could allow an external device to reset the circuit when desired.

the microcontroller's internal timer to produce 31 timer interrupts per half-cycle. Together with the full-off value, those interrupts provide the 32 power levels. Table 1 lists power level, corresponding voltage, and percentage of full on. A power value of 0 represents the lowest on voltage, 30 represents the highest, and anything greater than 30 represents a voltage of 0.0.

Eight bytes of RAM (PWRC0–PWRC7) function as control bytes, each corresponding to a Port B output bit. Each byte stores one item of power level data (as shown in column 1 of Table 1). To see how a value in a control byte is translated into an output voltage, follow this example.

Suppose that an application calls for a power level of 16 at Output 3, and a level of 30 at Output 7. In that case simply store values of 16 and 30 in control bytes PWRC3 and PWRC7, respectively. The outputs will immediately and simultaneously reflect these levels. Note that although the desired voltages were specified in decimal form, you must store the corresponding hexadecimal value in the output-control byte.

A "hole" was left in the microcontroller's EPROM (addresses $80–$5FF) for application programs. The five demonstration routines discussed earlier occupy those addresses. You are free to create your own applications, but leave the addresses outside that range alone. Addresses below $80 are reserved for constant and variable storage; addresses above $5FF contain the reset and interrupt routines. All 68705 registers, except for the timer, are available for use by application routines.

ASSEMBLER VARIATIONS

In developing the software for this article, the intention was to provide a single source file that would assemble correctly under three assemblers: the TECI 6805 Assembler, Motorola's 6805 Assembler, and Motorola's Freeware Assembler. In the course of testing, a bug was discovered in the Freeware assembler. After encountering an instruction that uses direct addressing on page zero of memory, the assembler starts generating garbage. Both of the other assemblers force extended addressing, thus avoiding the problem. The only point in the code where this is a problem is in the jump table, where there is the instruction:

```
JMAN: JMP MAN
```

By changing that instruction as follows, the problem can be avoided:

```
JMAN: BRA MAN
```

Branching, rather than jumping, works because the target routine is within 128 bytes of the jump table.

Construction

Assembly is straightforward. Figure 2 shows the parts layout on the single-sided circuit board. Load the board by inserting lowest- to highest-profile components. Make sure that you observe polarities of all semiconductors, SIP resistors, and electrolytic capacitors.

For the prototype, four Triacs were mounted each to two 90° aluminum heatsinks. The AC power input was brought to one heavy-duty, three-terminal connector, and the eight Triac outputs plus AC common were brought to a separate nine-terminal connector.

The circuit board has 120-volt AC signals on it, so check and double-check your work before plugging in and testing the project. Figure 3 is a photo of the author's prototype.

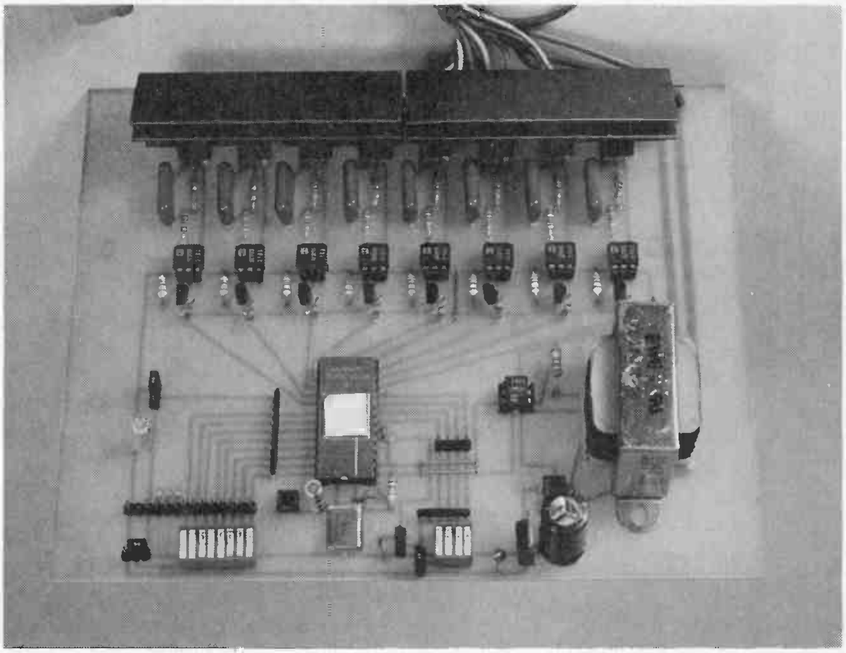

FIG. 3—COMPLETED UNIT. **The circuit board has 120-volt AC signals on it, so check and double-check your work before plugging in and testing.**

Built-in applications

On power up, a selection routine reads Port C and selects the corresponding application. Note that following power-up, Port C can be used for other purposes. Table 2 lists Port C values, along with the corresponding routines and PC-board jumper settings. In general, if no host is connected and Port A will input data from S1, set the jumpers as shown for application 0 (manual). Also note that in the design, once a routine has been selected, the only way to change to a new routine is to reset the system. The following is description of each in detail.

SOUND INPUT

The accompanying schematic shows a simple circuit for letting an audio sound source control the power-controller output. The circuit accepts input from a standard crystal microphone, and amplifies the signal using two op-amp stages. The signal then passes through an emitter-follower circuit that drives a TLC548 A/D converter. Potentiometer R10 functions as a sensitivity control.

The software, presented below, simply clocks the A/D converter eight times, accumulates the result, then stores it in all eight output registers, from where they are applied to the Triacs in the usual manner. To use the routine, you'll have to declare the variable SDDATA, add the routine itself to the jump table, and add a new S1 switch setting to the application-selection power-up routine.

Manual

The software scans Port A waiting for a bit to go low. When that occurs, the microcontroller loads power-level data from Port C and stores it in the power-control byte specified by the value in Port A. For example, placing 05 on Port C and bringing PA2 low will set output 2 to power level 8. Because Port C has only four input bits, it can only specify 16 power values ($2^4 = 16$). Thus a look-up table (shown in Table 3) spreads the 16 specifiable values across the entire 32-value range.

It started in America!

The creators are the masters in manufacturing the finest video products...

You probably don't associate VCR's with American technology. Fact is, video recording has its origins in America and it was 3M that brought video recording out of the lab and into your living room. Today, 3M video tape is the choice of all the major networks. No other tape company has ever won an Oscar or an Emmy. 3M Black Watch tape follows in this tradition—service and quality go hand in hand. Here are three Black Watch products you should be using at home!

Clean up! With constant playing and using of degrading dry or wet cleaners, the output of your video tapes has slowly diminished to an unacceptable level and the VCR plays as if it has a head cold! The culprit is most likely clogged and dirty video and/or audio heads. The 3M Black Watch™ Head Cleaner Videocassette uses a patented magnetic tape-based cleaning formation to remove head clogging debris. No foreign substances such as cloth, plastics or messy liquids and no harsh abrasive materials are present. The cleaner's usable life is 400 cleanings or more!

It's easy to use. Place the 3M Black Watch™Head Cleaner Videocassette in the VCR and press the Play button. A pre-recorded message will appear clearly on your screen and an audible tone is heard, telling you that the cleaning process is now completed. No guess work; you never over clean! Priced at $19.95.

For the VCR! Once your VCR's record and playback heads are cured, and the unit plays like new, consider using the finest videocassette you can buy—the 3M Black Watch™ T120 Hi Pro VHS 4410 Videocassette. The 4410 is the highest performing videocassette available today for use with all standard format VHS recording hardware!

Here's what you hear and see....A sharp, clear picture—brightest ever colors—freedom from streaks, flashes and snow—outstanding high-fidelity audio reproduction—optimum camcorder performance—maintains recording integrity. 3M Black Watch™ video tape is 100% laser inspected to guarantee surface smoothness and drop-out free performance. Priced at $8.00

You saw it here first! 3M Black Watch™ 0900 8mm video tape cassette loaded into your Hi Band camcorder delivers the finest picture and sound possible in the 8mm format. Extremely fine particles of pure iron alloyed with nickel and cobalt deliver a video performance exceeding 400 lines of horizontal resolution. You get the advantage of an exceptional video image with superior audio reproduction. This means your Hi 8 format camcorder will produce the best video and audio definition possible. With the 3M Black Watch™ 8mm cassette, the recording capability and performance of your camcorder will be significantly enhanced. Priced at $14.95.

POWER CONTROLLER

Continued from page 104

off. It then repeats that action for output 2, and so on. After output 7 toggles, the software then repeats the cycle.

Run and flash—This is a variation of the sequencer application. It sequences the outputs for five cycles, then flashes all eight three times and repeats the cycle.

Test—The test application tests the controller. The routine steps the outputs through all 32 power levels, pausing one second between each.

External—Here's where things get interesting. This routine allows an external source, such as an intelligent I/O module or a computer, to control power levels. To get into this mode, set switch S2 to a value of 2, install the correct jumpers, then reset the circuit. From then on, input Port C0 functions as a strobe that causes the microcontroller to read the value on Port A and perform the proper function.

When PC0 goes low, the microcontroller reads Port A. It then splits the value into a 5-bit power specification (PA0–PA4), and a 3-bit output port (PA5–PA7). The 5-bit power specification allows 1 of 32 values; the 3-bit output port allows 1 of 8 ports.

For example, assume you place the value $57 on Port A and strobe PC0 low. In binary, $57 = 0101 0111. Taking the upper three bits yields 010, or 2. Taking the lower 5 bits yields 10111, or 23. Thus the controller will set output 2 to level 23.

Summing up

As you can see, both hardware and software are simple and suitable for being customized. For example, you could connect the output of an A/D converter to Port A, then vary power levels based on some analog quantity.

When creating your own routines, be sure to include it in both the power-on Select routine and the Jump Table. That way the controller will know where to find it. Ω

THE PROJECT ANTHOLOGY

Continued from page 80

the circuit to be matched to the direct signal from the guitar.

A transconductance amplifier has an extra input, and it is this extra input that makes these components so useful in voltage-controlled filters and amplifiers. The output current is governed by the differential input current and the current fed to the control input. In effect, the gain of the amplifier is controlled by the current fed to the control input. In this case R13 is connected in series with the control input, so that it is voltage rather than current control that is obtained. R12 provides a small bias current to the control input under quiescent conditions. Without R12 there is a tendency for the output signal to decay a little too fast. Also, when the VCA provides very high attenuation levels the output signal seems to become heavily distorted, and produced a rather unmusical "buzzing" sound. R12 completely eliminates both problems.

The transconductance amplifier in the LM13700N has a fourth input, and this can be used to supply a bias current to linearizing diodes at the input of the amplifier. This enables higher signal levels to be handled. In this circuit R10 provides the bias current to the linearizing diodes. The LM13700N used for IC2 is actually a dual transconductance amplifier and buffer amplifier, but in this circuit only one amplifier and buffer stage are utilized. No connections are made to the other amplifier and buffer stage. Note that the LM13600N is virtually identical to the LM13700N, and will work just as well in this circuit.

Chip IC3 is used in the amplifier which drives the smoothing and rectifier circuit. This is an inverting amplifier which has its closed-loop voltage gain controlled by VR3. The maximum voltage gain is about 120 times, and this is obtained with VR3 at maximum resistance. The wide range of gains available should enable good results to be obtained using most guitar pick-up.

The rectifier and smoothing circuit is a simple half-wave type based on D7 and D8. Germanium diodes are used for D7 and D8 because they have lower forward voltage drops than silicon types, and they therefore give a DC output voltage which is a more accurate reflection of the input signal's amplitude. The attack and decay times of the smoothing circuit are kept quite short so that the output envelope accurately follows the envelope of the input signal. On the other hand, the decay time is made sufficiently long to avoid unwanted distortion products on the output signal.

The current consumption of the circuit is about 8 milliamps. This can be supplied by a 9-volt transistor radio battery, but it would be more economic to use a higher capacity battery (six AA cells or larger in a holder) if the unit is likely to receive a lot of use.

Adjustment. Adjust VR1 to give the best distortion effect. It is advisable to use the lowest resistance that gives good results, as higher resistances will give greater voltage gain, which will in turn encourage problems with feedback and general electrical noise. VR3 should be adjusted before giving VR2 its final setting. Adjusting VR3 is again just a matter of finding the setting that gives what is judged to be the best effect. Setting VR3 too low in value will result in rather a low-output level, and generally unimpressive results. Using a value that is too high will give plenty of output signal, but the initial part of the output envelope might be compressed slightly. This will give an output that is slightly lacking in terms of "twangyness." In between these two extremes there should be a fairly broad range of settings that give good results. Once VR3 has been given a suitable setting, VR2 is adjusted to balance the volume levels obtained with the effect switched in and out. Ω

MAGNETIC FIELD METER

short lead between TP3 and TP4. Adjust offset-null potentiometer R7 for 0.00. Remove the jumper, and the meter is complete.

Calibration

Calibration of the meter is basically determined by the pickup-coil characteristics, amplifier gains, and meter reference-voltage setting. The amplifier gains, as we previously discussed, are chosen to match the coil characteristics as closely as possible.

If you desire to calibrate your meter more exactly, you will need to generate a known magnetic field intensity. One way to do that is to pass a known current through a coil configuration whose field pattern characteristics are known. Figure 6 shows such a calibration setup. A good controllable signal source is a sine-wave generator and an audio amplifier, whose output is coupled to a coil through an 8-ohm resistor. Measuring the voltage across the resistor gives the current. Then, calculate the magnetic field according to Fig. 6. (Note that while all references to field strength here are made in teslas, gauss are also commonly used. The conversion is easy: 1 tesla = 10,000 gauss.)

Place the meter inside the coil and turn it on. Use the highest sensitivity scale that does not overrange the display. An overrange is indicated by a display of 1 followed by three blanks. In most cases, the 2 μT range is satisfactory.

Measurement interpretation

A great deal of controversy exists in the emerging understanding of potential health hazards of low-frequency magnetic fields. The International Radiation Protection Association (IRPA) has set some interim standards based on 1984 World Health Organization guidelines. Those IRPA standards specify a continuous maximum magnetic field exposure for the general public of 100 μT, and 500 μT as the maximum occupational exposure allowed over the entire working day. Ω

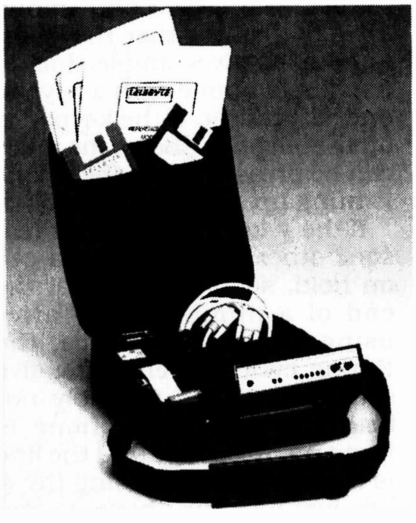
rate tester (BERT).

The Model 904 can be connected to any personal computer through any available serial port. The analyzer uses the serial port in a way that provides a high-speed data channel along with a serial control channel. The analyzer's embedded coprocessor permits the monitoring and emulation of data lines rated to 64 kilobytes per second on a full-duplex basis.

The Model 904 supports most WAN protocols, including asynchronous and synchronous protocols such as BiSync and IPARS, and bit-oriented protocols such as HDLC, SNA, and X.25. The protocol analyzer captures all parameters of the communications link: data, control leads, time stamps, and error conditions.

That information permits extensive post-capture analysis of data, even at a different location. Any combination of data line events can be searched or trapped. This allows the review of live data or search through captured data. Captured data can be saved as a DOS file on disk for later viewing, analysis, or printing. The included protocol emulator program interface allows the use of Telebyte off-the-shelf test analysis programs or the user can write his own custom programs.

In addition to monitoring, the Model 904 has emulation capabilities. A menu-driven program on the PC allows the selection of many combinations of communications options to emulate X.25, HDLC, Async, and BiSync. A built-in BERT tester offers a choice of test patterns and modes of operation. The analyzer is supplied with standard RS-232C monitoring software and two additional programs for X.25 and HDLC.



CIRCLE 45 ON FREE INFORMATION CARD

For portable field operation the Model 904 will run for 2 hours on a standard 9-volt battery. Since problems don't always happen in the same place, being able to hook up to the nearest PC without having to open the PC's case is convenient.

The Model 904, supplied in a carrying case with cables, software, and manuals, is priced at $499.00

perature of ice water (32°F) and 80°F water be the test points.

The temperature of the hot water can be determined accurately with a standard laboratory mercury thermometer, but a high-quality, liquid-filled confectioner's thermometer will also give satisfactory results.

Measuring temperature

Observe common sense precautions when measuring temperature with your digital thermometer. If the transistor/sensor is held near an open flame or heating coil it will be damaged or destroyed.

If you put the digital thermometer in a protective case to protect it from dust, rain, and salt spray, it will work reliably out of doors, in boats, or even on camping trips.

Keep the digital thermometer's temperature measurement limits in mind. The Harris ICL7106CPL has a rated temperature range of 0 and 70° Celsius. Ω

only eight). This approach checks all the functions of the 4017, including reset, clocking, clock enabling, and carry out. A second scan could be performed to sense the previously unchecked outputs instead of IC outputs 6, 7, and 8.

Most digital ICs can be tested in a similar process. That is, you must determine the necessary inputs to exercise all functions of the IC, program those inputs, determine where to observe the outputs and what those outputs should be. Then you can compare the results.

To make a simple jig for this purpose, you can use a general-purpose IC PC Board (Radio Shack Part No. 276-159) and a 20-pin IC socket. Solder the socket in place, and solder a solid wire loop on each of the input/output pads. The jig is shown in Fig. 16. Ω

Plant Trees for America™

Trees increase property values, and make our homes and neighborhoods more livable.

Trees provide food, shelter, and nesting sites for songbirds.

Trees help conserve energy. They cool our homes and entire cities in the summer, and slow cold winter winds. Shade trees and windbreaks can cut home utility bills 15-35%.

America needs more trees

The United States has lost a third of its forest cover in the last 200 years.

Our towns should have twice as many street trees as they have today.

We need more trees around our homes and throughout our communities. We need more trees to protect our farm fields and our rivers and streams. To provide wood for our homes and a thousand products we use every day.

10 Free Trees

Ten Colorado blue spruces, or other conifers selected to grow in your area will be given to each person who joins the Arbor Day Foundation.

Your trees will be shipped postpaid at the right time for planting in your area, February through May in the spring or October through mid December in the fall. The six to twelve inch trees are guaranteed to grow, or they will be replaced free.

You will also receive The Tree Book with information about tree planting and care.

To become a member and to receive your free trees, send a $10 membership contribution to Ten Blue Spruces, National Arbor Day Foundation, 100 Arbor Avenue, Nebraska City, NE 68410.

Join today, and plant your Trees for America!

ISOLATION TRANSFORMER

Continued from page 45

agram (Fig. 1) and begin the wiring by connecting the hot side of the line cord (black wire) to one side of the fuse holder. Next solder a wire from the other side of the fuse holder to one terminal of the main power switch, S1.

Connect the other terminal of S1 to the other side of the fan and to one terminal of S2. Connect power indicator NE1 across the fan terminals so it will indicate when power is applied to the fan and to S2.

Standby switch S2 allows power to the transformer to be shut off while still allowing the fan to work. Wire indicator NE2 across S2 so that it illuminates when S2 is open, or when the unit is in the standby mode. Next, connect S2 to the other side of the transformer. Connect the neutral (white) wire from the line cord to one side of the fan and also connect it to one terminal on the input side of the transformer.

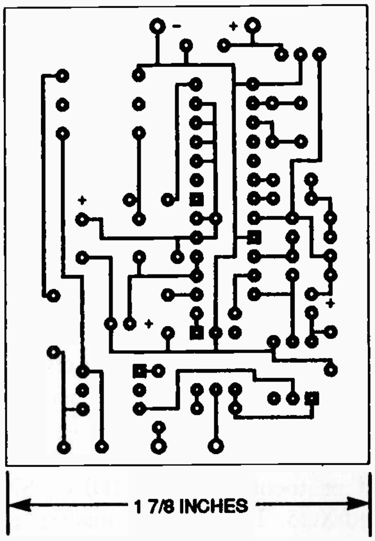
Connect both output leads of the transformer to the AC receptacle SO1. Next connect the output-power indicator NE3 across the receptacle. As a last important step, run a ground connection from the line cord (the green wire) to the base of the transformer and to the fan. If the transformer has not been grounded to the chassis, be sure to do so now with a separate wire.

Before closing up the case, plug an appliance such as a coffee maker, a lamp, or another appliance that draws about 500 watts into the isolation transformer outlet and turn on the power. Run the transformer with the load turned on for approximately 30 minutes while checking it every five minutes or so for excess heat.

The prototype was tested with an 800-watt coffee maker, and the transformer ran warm—but not hot—to the touch. Do not use the isolation transformer to power anything with that high a power rating for extended periods of time. Ω

PHONE ON HOLD

continued from page 38



FOIL PATTERN for the universal hold circuit's single-sided board.

the case.

Before closing up the case, connect the hold circuit to the telephone line and plug the wall transformer into an AC outlet. Pick a phone up, press the # key, and hang it up within five seconds; the LED should light. Pick a phone up and the LED should go out. Press the # key, wait about eight seconds, and hang the phone up; the LED should not light.

Operation

The power supply, DTMF decoder, and timing circuits are isolated from the telephone line by the optoisolators and transformer. The five-second timing cycle that starts after the # key is released gives ample time to hang up a phone with a keypad on the handset. If the keypad is on the telephone base, the # key can be pressed while the phone is hung up.

If the # key is pressed for reasons other than to place a call on hold, such as to signal the end of a number entry after using a fax-back service, the timing cycle will end after five seconds and will probably not be active when the phone is hung up. To be sure that the line is not on hold after using the # key, just pick the phone up and hang up again. Ω

THE COLLECTED WORKS OF MOHAMMED ULLYSES FIPS

#166—By Hugo Gernsback. Here is a collection of 21 April Fools Articles, reprinted from the pages of the magazines they appeared in, as a 74-page, 8½ × 11-inch book. The stories were written between 1933 and 1964. Some of the devices actually exist today. Others are just around the corner. All are fun and almost possible. Stories include the Cordless Radio Iron, The Visi-Talkie, Electronic Razor, 30-Day LP Record, Teleyeglasses and even Electronic Brain Servicing. Get your copy today. Ask for book **#166** and include **$16.00 (includes shipping and handling)** in the US and Canada, and order from **CLAGGK Inc., P.O. amplifier, a speaker, and a terminal strip. The signal generator circuit, shown in Fig. 12, consists of an astable 555 oscillator circuit, in which R1, in conjunction with C1 or C2, sets the output frequency. Switch S1 selects either the 0.01-µF capacitor that generates frequencies from 20 hertz to about 5 kilohertz, or the 1-µF capacitor that generates frequencies from 2 to 10 kilohertz. Potentiometer R3 controls gain or volume.

The audio amplifier circuit (Fig. 13) uses an LM 386 in a basic configuration. With just three components, a gain of about 20 is achieved; that can amplify the signal from a microphone, a Walkman-type radio, or any similar audio gear. The amplifier outputs about 500 milliwatts; if more power is needed, install an LM 380 amplifier IC that produces about 2 watts. Potentiometer R1 acts as a volume control by limiting the input voltage. The input and output to the amplifier are accessed from the terminal strip, as are the speaker and signal generator. This circuit is so simple that point-to-point wiring is used, as shown in Fig. 14.

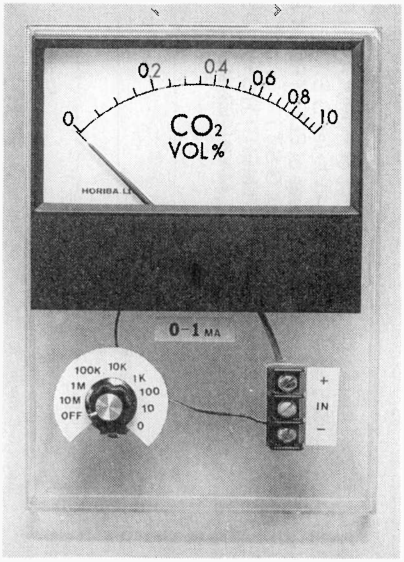

FIG. 18—THE METER MODULE contains a factory-made 0- to 1-milliampere movement.

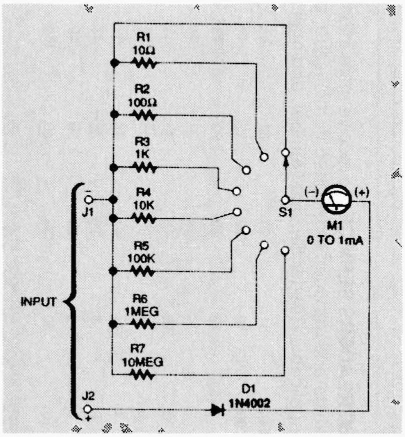

FIG. 19—AN 8-POSITION ROTARY SWITCH allows the input to be connected either directly to the negative meter pole, or through one of seven dropping resistors.

The three-digit decoder-driver shown in Fig. 15 adds another practical function block. The circuit, shown in Fig. 16, will interface with any standard BCD output to produce a digital display. The circuit contains a CD4553 three-digit BCD counter and a 74LS48 seven-segment decoder. The decoded data is routed to a three-digit, common-cathode display.

A logic probe is also included in the BCD decoder module. This simple circuit will indicate logic status, either high or low, at any given test point. Figure 17 is the schematic of the logic probe, which lights the red LED (LED2) for high logic levels, and the green LED (LED1) for low. If desired, common-anode, seven-segment displays can be substituted for the single LEDs. The cathodes of the b, c, e, f, and g segments of one display can be wired together to form an "H" to indicate a high, and the f, e, and d segments of the second display can be wired together to form an "L" to indicate a low.

The meter module shown in Fig. 18 makes use of a factory-marked 4½-inch, 0- to 1-milliampere movement, bought at surplus. As shown in Fig. 19, an 8-position rotary switch (S1) allows the input to be connected either directly to the negative meter pole, or through one of seven dropping resistors ranging in value from 10 ohms to 10 megohms. When using this meter, it is best to start with the highest setting, and then work down to prevent pinning the pointer. Ω

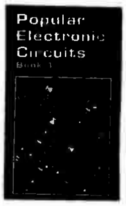
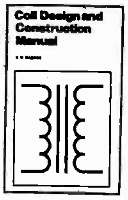
Hobbyist's Paperback Budget Books



☐ **BP80/98—Popular Electronic Circuits-Books 1 and 2...$11.90.** Contains a wide range of circuits which are accompanied by text giving a brief introduction, circuit description and special notes on construction and setting-up that may be necessary.



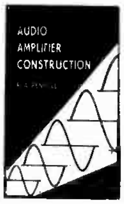
☐ **#160—Coil Design and Construction Manual...$5.95.** A complete book for the home builder on how to make RF, IF, audio and power chokes and transformers. Practically every possible type is discussed and calculations are explained in detail.

☐ **BP271—How to Expand, Modernize and Repair PC's and Compatibles...$7.75.** All the practical information you are likely to need to upgrade your PC and compatible. Also contains useful information and illustrations to help you with repairs.

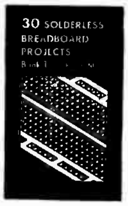
☐ **BP276—Shortwave Superhet Receiver Construction...$6.95.** Provides construction details, including coil winding, of a number of advanced-design receivers which should have performance levels at least equal to commercial sets of similar complexity.

50 Projects Using IC CA3130

☐ **#223—50 Projects Using IC CA3130...$5.00.** One of the more practical and useful operational amplifiers (opamp), the CA3130 integrated circuit chip is the heart of several easy-to-assemble projects covered in the book. The projects are divided into five categories: audio projects, RF projects, test equipment, household projects and a catch-all miscellaneous group. Ideal for all skill levels.



☐ **BP122—Audio Amplifier Construction...$5.75.** Practical designs are featured and include circuit diagram and description, Veroboard or printed-circuit board layout and construction notes. The text is divided into two parts. The first deals with many types of preamplifiers. The second covers power amplifiers from a simple low-power battery type to a 100-watt DC-coupled amplifier using four MOSFETs in the output stage.

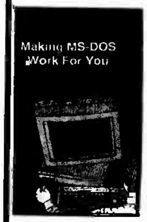


☐ **BP107—30 Solderless Breadboard Projects-Book 1...$5.95.** Each project is designed to be built on a "Verobloc" breadboard and is presented with a brief circuit description, circuit diagram, component layout diagram and components list. Notes on construction and applications are provided. Wherever possible, the components are common to several projects to keep project costs down.

☐ **BP266—Electronic Modules and Systems for Beginners...$7.25.** Shows the reader how to build a number of simple analog and digital circuit modules, all suitable for battery operation, and all based on only 1 or 2 transistors or ICs.

Electronic Music Learning Projects

☐ **BP329—Electronic Music Learning Projects...$6.25.** A beginner's book that will assist you in assembling such projects as the Elexylophone, Gildaphone, Melody Ranger, Cordmaker, Appealing Handbells, Electronic Sol-Fa, Tune-up Box and more.



☐ **BP319—Making MS-DOS Work for You—$6.50.** What you need to know first, comes first, however the text is written in a circular style so that the reader can start anywhere in the text. This book is relevant to all versions of both MS-DOS and PC-DOS.

UNDERSTANDING PC SOFTWARE
SOFTWARE

☐ **BP303—Understanding PC Software...$6.95.** Covers main types of PC software, giving details of typical uses, the basics of how they are used and their limitations. Each chapter covers popular software and programs of a similar type.

Aerial Projects

☐ **BP105 Aerial (Antenna) Projects...$5.50.** In this book the author has considered practical antenna designs, including active, loop and ferrite antennas which perform well and are relatively simple and inexpensive to build. The complex theory and mathematics of antenna design have been avoided. Also included are construction details of a number of antenna accessories including a pre-selector, attenuator and filters.

Electronic Calculator Users Handbook

☐ **BP33—Electronic Calculator Users Handbook...$5.75.** The book eliminates the mysteries of the calculator and offers unique ideas for the simplest to most complex calculators. Covers the basic functions plus trigonometric, hyperbolic, logarithms, square roots and powers. Included are formulas and data for VAT, discounts, and mark up, currency conversion, interest, binary and octal numbers, and much more!

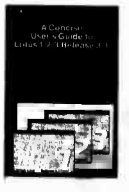
☐ **BP125—25 Simple Amateur Band Antennas...$5.50.** Plans to build antennas that are simple and inexpensive to construct and perform well. From the simple dipole to beam, triangle and even mini-rhombic types made from four TV masts and about 400 feet of wire. After the antenna discussion you will find a complete set of dimension tables that will help you "tune" an antenna on a particular frequency.

A Concise Introduction to dBASE

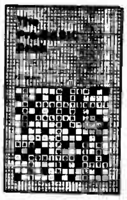
☐ **BP263—A Concise Introduction to dBASE...$6.95.** The most popular data-base program, dBASE, is difficult to master without help. This book helps you spend your time using dBase, not setting it up. A user's guide that covers all the basics up to dBase IV.

Electronics

☐ **PCP104—Electronics—Build and Learn...$9.95.** Construction details are given to build a circuit demonstrator that is used throughout the book to introduce common electronic components and how these components are built up to useful circuits.



☐ **BP302—A Concise Users Guide to Lotus 1-2-3 Release 3.1...$6.25.** Written to help existing spreadsheet users upgrade to 1-2-3 Release 3.1, which has the ability to work 3-dimensionally with both multiple worksheets and files.



☐ **BP146—The Pre-BASIC Book...$6.95.** Another book on BASIC but with a difference. It concentrates on introducing technique by looking in depth at the most frequently used and more easily understood computer instructions.

Just What the Project Builder Is Looking For!

☐ **#160—Coil Design and Construction Manual**	**$5.95**
☐ **#219—Solid State Novelty Projects**	**$4.95**
☐ **#222—Solids State Shortwave Receivers for Beginners**	**$5.50**
☐ **#223—50 Projects Using IC CA3130**	**$5.00**
☐ **#225—Practical Introduction to Digital ICs**	**$5.25**
☐ **PCP111—Electronic Test Equipment Handbook**	**$13.95**
☐ **1596T—24 Silicon-Controlled Rectifier Projects**	**$9.95**
☐ **BP58—50 Circuits Using 7400 Series ICs**	**$5.50**
☐ **BP69—Electronic Games**	**$5.50**
☐ **BP71—Electronic House Projects**	**$5.00**
☐ **BP84—Digital IC Projects**	**$5.50**
☐ **BP93—Electronic Timer Projects**	**$5.50**

Preface

This book is for those of you who want to learn about electronics and computers but frankly are put off by all the gory details. If you have a short attention span, a nonexistent background in science, math, and technology, and are looking for near-instant gratification of electronics knowledge, this book is for you. Electronics is a complex subject, especially if you want to be an electronics engineer. However, if you are merely curious or just need a working knowledge of electronics for your job, this book will give you a basic education on the fundamentals without boring you to death or loading you down with the excruciating details that other books lay on you. What I have attempted to do is write a book that tells you the most important concepts and fundamentals but leaves out the minutiae that only an engineer will need or appreciate. This book contains exactly what you need to know today in the 21st century.

There are lots of basic electronics books around and you may already have read some. This one is really different. First, it does not go into detailed circuit analysis. Why? Simply, all electronic equipment today is made up of integrated circuits or chips, and we can't see the circuits, access them, or even repair them. If you are an electronic engineer designing integrated circuits, yes, you do need to understand their operation. If you just want to learn how electronic equipment works, then you can skip this detail. This book treats circuits as simple functional building blocks whose purpose and application are easily understood.

Second, this book presents what I call the NEW electronics. Most basic electronic books dwell on the older components and circuits and ignore how electronics really is today. These books do a good job teaching you the history of electronics but little else. What you will see in this book is a fresh new way to look at and understand electronics, especially in the context of the familiar applications you use every day made with the most advanced integrated circuits. If you complete this book and still want more, one of the more traditional basic electronics books would be your next step. See the appendix for my recommendations.

The first three chapters introduce you to the electrical principles that form the basis of electronics. You will learn the core concept of electronics, which boils down to how to generate current flow and then control it to do something useful. Magnetic fields are also covered, since magnetism is just as important in electronics as current flow. But don't worry, even if you never took a physics course you can easily get through this material.

Next, you learn about the basic components of electronics such as resistors, capacitors, inductors, transformers, diodes, transistors, and especially integrated circuits. Then you will discover all the different types of electronic circuits used to make up any electronic device. The functional block diagram approach is used here so you won't have to do the nitty-gritty circuit analysis that has you chasing electrons through components and solving simultaneous equations.

An important part of this book is the coverage of computers, and specifically of embedded controllers, that is, those tiny single-chip microcomputers or microcontrollers that are built into virtually every electronic device. Digital signal processors (DSPs) are also covered since they also appear in most modern electronic equipment. You can't name an electronic product today that does not have one of these embedded computers in it. You really need to know what these are and how they work, as they are the very heart of electronic devices today.

The rest of the book consists of descriptions of how all the major electronic products and systems work. The entire range of modern electronics is covered, including major things like cell phones, TV (cable, HDTV, DVD, VCR, etc.), audio (stereo, CDs, MP3, etc.), satellites (GPS, TV, radio, etc.), radio (broadcast, marine-aircraft-shortwave, ham, CB, family radio, etc.), and everything else you can think of. And it is all explained using basic building blocks rather than detailed circuits.

Finally, if you want involvement as you read the book, get involved with the projects that I list in the Project sidebars in each chapter. These can lead to a deeper understanding of the concepts. Furthermore, these projects could encourage you to become a true electronic hobbyist … or is that a geek or nerd?

When you finish this book you will not be an electronic engineer nor will you be able to design or analyze circuits. But you will know about all the different kinds of circuits, how they work, and how they all fit together to create electronic equipment. The benefits to you are the ability to apply, use, select, operate, and to some extent troubleshoot most of the common electronics products with confidence, while appreciating their complexity and the value they deliver. Hope you like it.

Chapter 1

Learning about Electronics for Your Own Good

A Little Bit of Perspective before You Get to the Details

In this Chapter:

- Why it is helpful to know electronics.
- The 10,000-foot view of the electronics industry and how it works.
- The systems view of electronics.

INTRODUCTION

You don't know how lucky you are. You live in high-tech heaven surrounded by lots of useful, entertaining, interesting, necessary, and even addicting electronic products, products you cling to and would not want to give up.

But do you have any idea how many electronic products you own? Do you really know how much electronics influences your life every day? Some of you do, but most of you probably do not because your electronic gadgets are pretty much taken for granted. Yet we spend the better part of our lives working with these devices. Most of us sit in front of a computer all day at work, slouch on the couch in front of the TV at night, listen to our iPods going to and from work, and spend a weekend downloading videos off of the Internet or taking photos with a digital camera. And let's be clear here, how many text messages did you send today or cell calls did you make? The impact on our lives of all this electronic equipment is almost overwhelming. In this first chapter, I encourage you to think about how electronics impacts your life.

And that brings us to the subject of this book, learning how electronics works. If you want a first book in electronics that gives you the big picture about how electronic equipment works, this is it. I am not going to beat you to death with a lot of complex circuits and theory or math, only what you really need to know. Then I will go on to show you how each and every one of the products you use every day actually works.

IT ISN'T LIKE IT USED TO BE

It used to be that you learned electronics by playing around with resistors, capacitors, transistors, and other devices. You wired up simple circuits, built a one- or two-transistor radio, or even built a kit. But today electronics is so different that it is hard to do that anymore. Oh yes, you can still build little circuits and radios and other gadgets, but that is not how electronic products are made today. Electronic equipment today is made with integrated circuits or ICs that we also call chips. These chips are tightly packed on printed circuit boards with resistors and capacitors that you can barely see. It is more difficult than ever to experiment with these devices, much less troubleshoot and repair them. We are in that age of electronics where unless it is a big pricey piece of equipment, you throw a defective electronic product away and simply buy a newer and better one at a lower price.

But despite the complexity of today's electronic products, there is something just fascinating about them. Many of you actually want to know how they work. And despite their complexity, these products are actually understandable. It is possible to learn how these devices work without a whole lot of trouble. And you don't have to learn all the math and physics required by engineers to do so. This book takes the basic ideas of electronics and reduces them down to the lowest common denominator and shows you how to use those fundamentals and apply them to all of the fabulous electronic gadgets you have today.

WHAT'S IN IT FOR YOU?

There are some big benefits to being electronic literate. Take a look at some of them.

Satisfy Your Curiosity—Surrounded by so much electronics, you often probably wondered just how all this stuff works. For some of us, not knowing how something works nags at us until we satisfy that curiosity. If you have an interest in electronics, you tend to want to know more about it. This book will get you started in the right direction.

Enhance Your Hobby—If you dabble in a hobby that uses electronics, you obviously want and need to know more about it. Lots of hobbies involve electronics such as radio-controlled models, electric trains, amateur radio, shortwave listening, citizens or family radio, audio systems, or video. Or maybe you just like playing around with your home security system, garage door opener, or your high-speed Internet connection. A major part of any hobby is learning more about it and that is very satisfying. And don't forget—electronics itself can be your hobby. You can spend your time learning more about it and then digging deeper into those things that you want to know more about. Amateur radio is certainly one of those electronic hobbies that will take you from one extreme to the next in the radio spectrum. Anything having to do with computers is also a great hobby.

With everything being controlled by an embedded microcomputer, spending more time learning about them is a great activity with nearly endless possibilities.

Job-Related Needs—You may actually be working in a job surrounded by electronic equipment of some sort, yet you do not know how it works. Often, just understanding some of the fundamentals will give you a better grasp of how to use that equipment or even troubleshoot and repair it. Understanding some of the concepts may actually help you to better select and purchase equipment that you may use.

Boost Your School Performance—For those of you going to a college or university to learn electronic engineering or technology, you regularly have your curiosity stimulated by the classes you take. Yet most of the classes are heavily involved with theory, physics, math, and circuit analysis. What you really don't get in school is the perspective or big picture as to how the electronic products actually work. This book will give you the big picture and show you how it all comes together so that all those detailed classes in circuits and theory will make more sense.

Just so You Won't Appear to Be So Dumb—With electronics everywhere, people often talk about it without really knowing what they are talking about. It is amazing the ignorance of people who use the electronics but don't have a clue as to what it does or how it does it. For instance, do you really understand what an MP3 is, or why BluRay DVDs are better, or what a 3G cell phone really is? The answers are in this book. If you want to appear a little smarter to your co-workers, friends, and relatives, this book can help out. You will be able to deal with common questions and misconceptions, such as can you get shocked by a car battery, can you really get brain cancer or pop popcorn with your cell phone, or will sitting too close to your TV set make you sterile? While this book certainly won't make you a genius, it will indeed give you the basics so that you won't appear to be an idiot when technical questions about electronics come up.

ELECTRONICS: THE BIG PICTURE

Before we get into the nitty-gritty of how electronic equipment works, you really need to know the entire scope of electronics. It is a huge industry and recent figures seem to show that it is one of the biggest, if not the biggest, markets in the entire world. To get a grasp of how big the industry is, we normally break it down into segments of specializations. There are five major fields of electronics: communications, computers, control, instrumentation and measurement, and components. Any electronic product or device will easily fall into one of those categories. In some cases, the product may overlap two or more or all of those categories. Take a look at Figure 1.1, which shows each of these segments of electronics and the products and technologies that are part of them.

Communications

Communications is the oldest segment of electronics and still the largest. Electronics actually started with communications–specifically telegraph, telephone, and radio–and grew from there. A lot of this book is about communications because it is such a huge segment of the industry and one that we use the most. And don't forget, communications comes in both wired and wireless forms. Wired systems include the vast telephone network, cable TV systems, and computer networks, including the Internet. Wireless systems comprise all of the radio, cell phone, television, satellite, radar, and other wireless systems.

Computers

Computers have only been around since the late 1940s and early 1950s but what an impact they have had on the way we work. Today virtually everyone uses and even owns a personal computer. And then there are all the larger and more powerful computers such as the servers that manage all of our networks, the mainframes still used by government and big business to manage huge databases, as well as the high-speed supercomputers that still do an amazing amount of scientific, engineering, and mathematical design and research. But the computer we are going to talk about most in this book is the embedded controller. These are small single-chip digital computers called *microcomputers* or just *micros* that are literally part of every electronic product. These are miniature digital computers dedicated to a specific function inside the products in which they exist.

Control

Control is a broad general term for monitoring and control. Monitoring, of course, means sensing various physical characteristics such as temperature, humidity, physical position, motor shaft speed, or light level. Electronic devices called *sensors* or *transducers* convert these physical characteristics into electrical signals which allow us to monitor them. Control refers to managing and exercising some degree of influence over items such as motors, lights, relays, heating elements, and other devices. Most monitoring and control functions take place in factories, chemical plants, refineries, and food processing operations. Control also occurs in the home, an example being your electronic thermostat. It also shows up in electromechanical products like a DVD player. Electronic controls appear in appliances, home control systems, security systems, automobiles, and even toys. Robots are another major segment of the control industry.

Instrumentation

Instrumentation refers to the field involved with testing and measuring electronic equipment and other mechanical or electronic items. It refers to the test instruments like volt meters, oscilloscopes, and spectrum analyzers as well as the large automated test systems used for mass testing and measuring of other devices. Instrumentation refers to data acquisition systems, medical tests and measurements, and a wide range of other products.

Components

All of the electronic products that make up each of the four major segments of the electronic industry are made up of various electronic components. In the past, electronic products were made of the individual discrete components such as resistors, capacitors, diodes, and transistors. Today most electronic equipment is made with one or more integrated circuits surrounded by a sprinkling of those other so-called *discrete* components. No longer can we access most individual components or circuits since they are sealed within integrated circuits or chips. Just keep in mind that there is a whole industry centered on making these electronic components that are in turn made available to the manufacturers of the end electronic equipment in each of the four major categories just described.

HOW THE ELECTRONICS INDUSTRY WORKS

As part of the big picture of learning electronics, you really need to understand how the industry itself works. This is summed up by the simplified block diagram in Figure 1.2. It all starts with the raw materials that the component manufacturers use to create the individual components. For example, sand is refined into silicon, which, in turn, is converted into wafers that are processed into the integrated circuits we use.

The electronic equipment manufacturers design the electronic equipment for the marketplace. It may be a TV set, a cell phone, or a military radar. These companies buy the electronic components and put them together to create the

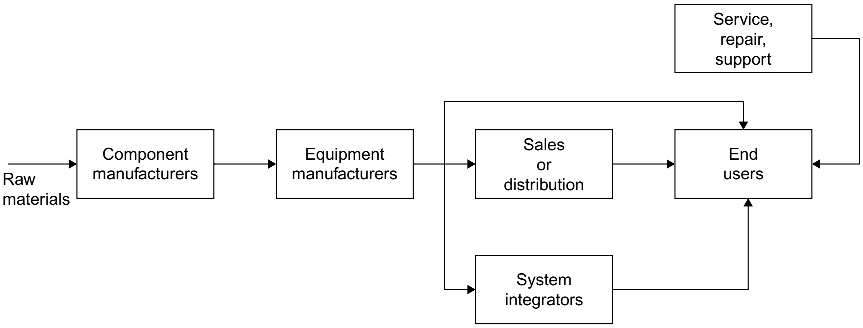

FIGURE 1.2 General block diagram of how the electronics industry works from raw materials to end users.

end product. Manufacturers may then sell the end product directly to customers and end users. In some cases, the end product will go through a sales organization or distributor of some sort. Your LCD large-screen TV set doesn't come directly to you directly from Samsung in Korea or Sony in Japan. It is sold to an organization such as Best Buy or Circuit City, which is where you buy it. Sometimes the electronic equipment is sold to so-called systems integrators. These are companies that piece together larger systems for an end user (like the military) made up of a wide range of different types of equipment.

Finally, there are the customers or end users of the equipment. These come from a wide range of backgrounds. The end users or customers may be businesses with offices, industry with factories and process control plants, or the government, military, hospitals and other medical organizations, schools, colleges and universities, and you the consumer. There is also a network of service companies designed to support customers. They may do installation or repair work that the customer is not capable of doing.

Electricity versus Electronics

One of the questions that always comes up in the early stages of learning about electronics is what the difference is between electricity and electronics. Let's get this straight up front. Electricity refers to the basic energy we use for power. It generally involves the generation and distribution of electrical energy to homes, businesses, and factories. Electricity is energy that is produced by the coal-fired or nuclear power plant and then sent to you over long transmission lines until it comes into your house where you access it through your AC wall outlets. You use that energy for lighting and appliances, and also to power most of your electronic equipment.

Electrical power may also be generated for use in other systems. The electrical system in a car is a great example. It uses a battery plus a generator driven by the automobile engine to recharge the battery and to operate all of the electrical and electronic devices in a car. Ships, airplanes, and off-shore drilling rigs also have their own electrical-power generating systems. The new electric wind generators and solar power systems are also electricity-producing systems.

All of the principles of electricity also apply to electronics. Basic electrical components such as resistors, capacitors, inductors, transformers, motors, and other similar devices are also used in electronics.

Electronics is the field of science that uses electrical principles to perform other useful functions. Electronics is the control of electricity to produce radio, television, computers, robots, and MRI machines. To control the electricity, you need more than just basic electrical components such as resistors and capacitors. What makes electronics possible are the unique components called *transistors*. Electronics began, of course, with vacuum tubes and then switched over to transistors as the main control devices. Transistors are now miniaturized and packaged in devices called *integrated circuits* that perform very specific electronic functions, such as generating signals, amplifying signals, or performing some control function. Just keep in mind that it is the control devices such as transistors and the circuits that they comprise that make electronics what it is. The transistors are used to form circuits that in turn perform all of the various functions required to produce electronic devices.

THE PAINFUL TRUTH

Okay, here comes the hard part. Electricity is moving electrons. An electron is a tiny particle that is inside the atoms that make up everything we can feel, see, and even not see. If we can get some electrons moving together in a wire, electrical or electronic component, or circuit, we can control them to do many useful things, such as amplification, for example. Moving electrons make up what we call *current flow*. And current flow is produced by electrical energy called *voltage*. Voltage comes from batteries, the AC wall outlet, and lots of other sources including power supplies, solar cells, microphones, and the like. If we can control the electrons we can produce magic results. That is what electronics is all about.

We control the electrons with components like resistors, capacitors, inductors, transistors, and all sorts of integrated circuits. We create circuits that actually process the electron flow. We can call the voltages that create current flow and the resulting current *signals*. The circuit processes the signals to produce the end effect that we want, be it a radio, a computer, or DVD player.

One of the basic models I will use in this book is shown in Figure 1.3. Think of electronic signals as the inputs to a circuit or piece of equipment that processes the signals producing new signals that represent the output we want. Think of the small voltage that comes from a microphone when you talk into it. It is basically too small to be useful. So we apply it to a circuit called an *amplifier* that makes the signal bigger and more useful. That amplifier processes the signal to make it large enough to drive a speaker as our desired

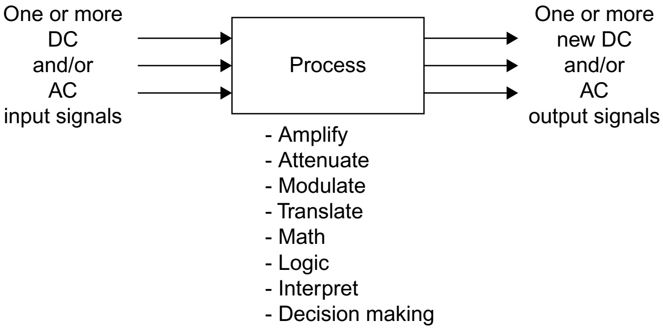

FIGURE 1.3 Model of how all electronic circuits and equipment work. Input signals are processed by circuits and equipment into new output signals.

output. The result is a public address system. Anyway, you get the picture. Just remember that *all* electronic circuits and equipment are based on this model: INPUT-PROCESS-OUTPUT. Think about it.

Here are a couple of other examples to show how most electronic things work.

Cell Phone

Take a look at Figure 1.4. On the left is a cell phone handset. It is made up of two major pieces–a transmitter (TX) and a receiver (RX). You talk into a microphone and generate a small electrical voltage or signal representing your voice. The transmitter takes that and processes it in such a way that the voice controls or modulates a high-frequency radio signal. That signal carrying your voice is then radiated by the antenna to a cell site or base station. The base station receiver picks it up and processes it back into the original voice signal where it then undergoes other processing before being sent over the telephone network to its destination. The dialing process or text messaging from the keyboard also generates input signals that are transmitted to the base station.

On the return side, the voice from your caller passes through the cell phone network to the base station and it is then used to control the transmitter to send that voice to you by radio. The transmitter sends the signal to the antenna that sends the signal to the receiver in your cell phone. The receiver processes the signal by amplifying, demodulating, and otherwise processing the voice that eventually is sent to the speaker that is glued to your ear. Another output may be a text message on the liquid crystal display (LCD).

Computers

The main function of a computer is to store and retrieve data, process data, and to provide automatic control. Data consists of information, facts, and figures. It may be numbers, letters, symbols, or text of any kind. It might represent

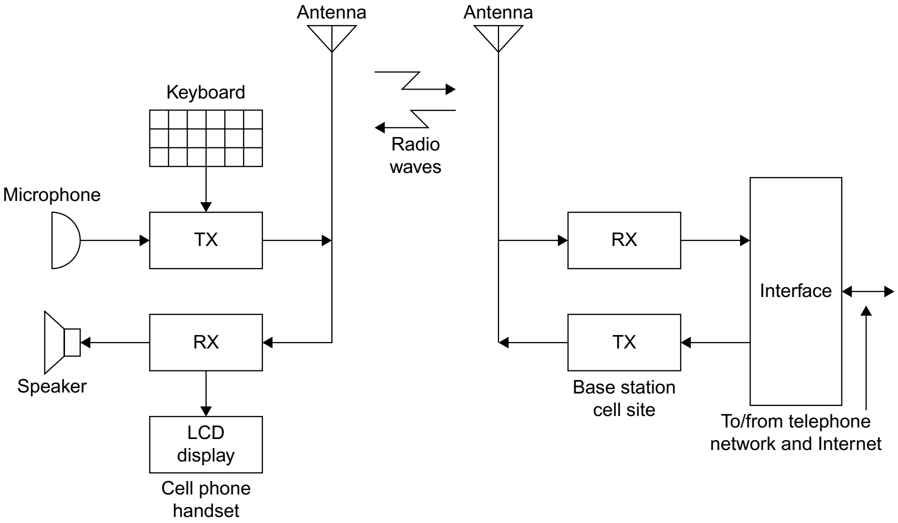

FIGURE 1.4 Model showing how a cell phone communicates with a cell site to make a call.

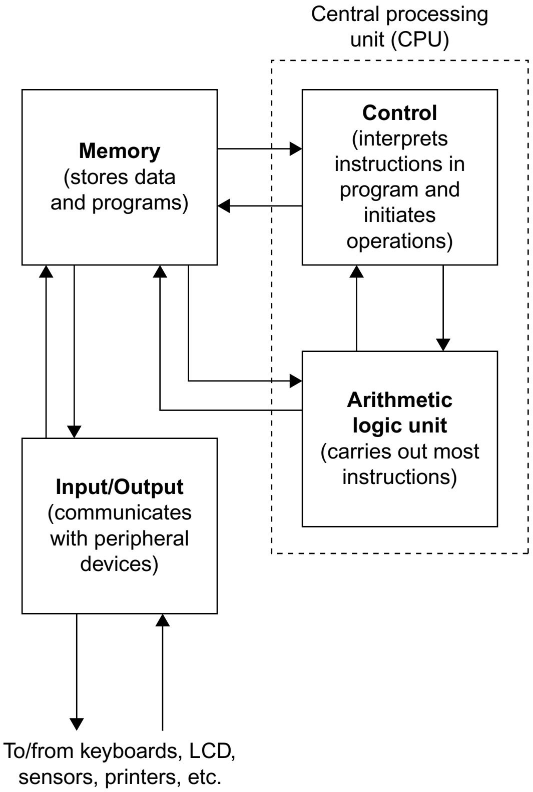
names and addresses, parts inventory, accounting or banking figures, control signals, or a variety of other items. Data may also be graphics and illustrations, or voice and video that are converted to data. Such data can be stored electronically in computers and rapidly accessed.

Computers process or manipulate data in many different ways. They can perform mathematical operations on it, sort it, edit it, translate it, or otherwise operate upon it to produce some useful output. Computers also make decisions based on the data.

Computers have so many applications that it is difficult to enumerate them. In general, computers are tools that help people organize and perform their work in a more efficient manner. Computers also allow people to do work that was difficult or impossible to do without computers. Computers perform accounting and banking operations; store and process mailing lists and employee records; solve complex mathematical problems in business, science, and engineering; and create graphics. The thing that makes them so valuable is that all of their operations are automatic. Humans need not be a part of the actual computation, as is necessary with a calculator. Computers carry out preprogrammed assignments to solve various problems or perform operations. Most operations are extremely fast. It is this automatic feature that makes computers so useful.

All computers, regardless of their size and features, are made up of the four basic sections shown in Figure 1.5. The memory electronically stores the data to be processed, as well as the program that tells how the data is to be manipulated. The program is a sequence of codes or instructions that cause the computer to carry out its preprogrammed assignment one step at a time.



Central processing unit (CPU)
Memory (stores data and programs)
Control (interprets instructions in program and initiates operations)
Arithmetic logic unit (carries out most instructions)
Input/Output (communicates with peripheral devices)
To/from keyboards, LCD, sensors, printers, etc.

FIGURE 1.5 Block diagram representing any digital computer, be it a mainframe, PC, or embedded controller.

Refer again to Figure 1.5. The control section examines the program instructions one at a time in sequence, interprets them, and then sends control signals to all other parts of the computer. The desired operations, such as store, add, print, and so on, are carried out.

The arithmetic logic unit (ALU) is the section that actually carries out most of the processing. It performs data transfers, arithmetic operations, and logical decision making. In most computers, the control and ALU sections are integral units that work closely together. They are usually referred to as the central processing unit (CPU). A microprocessor in a personal computer is a single chip or central processing unit.

The input/output (I/O) section in Figure 1.5 is the interface between the computer and the outside world. It communicates with peripheral devices that humans use to input programs and data, and receive the output results of computation. Data and instructions are usually entered via a keyboard, while outputs are displayed on a video screen or printed out. Inputs may come from sensors and output may go to a printer or LCD readout.

There are many sizes and types of computers. Supercomputers are the largest and fastest computers. They are used primarily for difficult, complex scientific and math problems. Mainframe computers are also very large, and they are used by business and government for financial applications, data storage, and other applications. Personal computers are the smallest practical computers in use. Millions of them are used for word processing, financial spreadsheets, database management, and email and Internet access.

There are also many dedicated computers, built into other equipment to perform single-purpose operations unlike the general-purpose data processors described above. Thanks to semiconductor technology, it is now possible to put an entire computer on a single chip you can hold in your hand. These are called *embedded computers*, or *microcontrollers*. These microcomputers are used like components and are built into most other kinds of equipment such as TV sets, microwave ovens, gasoline pumps, washing machines, and many others. Virtually every other electronic product contains at least one or more embedded controllers. And even very large ICs have controllers on the same chip called *cores*.

Robots

A great example of a control device is a robot. Most robots consist of an electromechanical manipulator arm used in manufacturing operations. Robots are machines designed to mimic human capabilities. Most robots simulate a human arm and hand. As a result, a robot may be able to substitute for a human in certain manufacturing jobs. A typical robot manipulator arm is shown in Figure 1.6. Motors operate shoulder, elbow, and wrist joints, while grippers and other tools form the hand that does the work.

Robots help automate the manufacturing process to increase productivity. They lower costs, produce more goods in less time, and improve quality. Robots also replace humans in many jobs requiring repetitive, tedious, and hazardous work.

Robots perform a variety of tasks in industry. The most common are welding, spraying or painting, and “pick-and-place” operations. Various tools on the end of the manipulator arm, called *end effectors*, let the robot perform a remarkable variety of tasks. In addition, a programmable controller or computer is used to control the robot. A robot may thus be programmed to perform a wide variety of jobs and is easily reconfigured when the work changes.

In subsequent chapters you will see more of these kinds of descriptions. But in Chapters 2, 3, and 4, you will learn a few more basics that make the rest of the book more understandable.

Project 1.1

How Much Electronics Do You Own?

Just to be sure that you really appreciate the extent to which electronics impacts your life, I strongly suggest that you take a few minutes and make an inventory of all the electronic devices and equipment that you use at home, at work, and away from home. Get a yellow pad and a ballpoint pen and move around your house and just write down all the electronic products that you own and use on a regular basis. TV sets, computers, and cell phones are the most obvious, but don't forget things like telephones, your wrist watch, appliances, and other entertainment products. Make a separate listing of the electrical and electronic products you use inside your car and then another one for those electronic products that you use at work. Make the list comprehensive. Study it. Be amazed.

Project 1.2

How Much Electronics Do You Use?

Now take that same pad of paper and pen and make a quick summary of how you spend your time during the day. How much time do you spend using each of the electronic products that you listed above? Some of them are only momentarily used, but others you use over longer periods of time, particularly computers and TV sets. Just take a quick estimate of the time you use each one during a typical day. Again, add up the hours. Be amazed.

Project 1.3

Decisions, Decisions

Make the following decision. If you had to give up all of your electronic products but one, which one would you keep? TV, cell phone, remote control, iPod? Only one. This will say a lot about who you are.

Chapter 2

Electronic Concepts: More Interesting Than You Think

Some Basic Stuff You Really Need to Know

In this Chapter:

- Electrons and current flow.
- DC and AC voltage.
- Voltage sources, batteries, the power line, and power supplies.
- Signal sources.
- Magnetism and induction.

INTRODUCTION

You don't have to be an engineer, physicist, or mathematical genius to learn electronics. But there are a few basic things that you need to know so you can understand what is going on in the circuits and equipment. For example, you need to know that electrons are what makes up current flow, and voltage is what makes the current flow. You also need to know about magnetic fields and electric fields, where they come from, and what they do. And how magnetism and current flow are related. With that background you are ready to learn about the various components and circuits. This chapter takes care of those basics.

ELECTRICITY AND ELECTRONICS

Electricity is a type of energy produced by a charge that is either fixed (static) or moving (dynamic). The main source of electricity is the electron, a subatomic particle that has a negative charge. When electrons are stored or moved, electricity is produced.

Electricity is one of our prime sources of energy. It is used for lighting, heating, and operating appliances of all sorts. It powers motors to produce mechanical energy, and it powers our electronic equipment. The uses of electricity are virtually infinite.

Electronics is the field of applied science that uses components such as resistors, capacitors, diodes, transistors, and integrated circuits to control and process electricity. These components are used to create circuits that convert, modify, vary, translate, or otherwise manipulate electrical charges to perform useful functions. That is the essence of it. Now for the details.

Atoms and Electrons

This section really ought to be called Physics 101 but I don't want to scare you away. Just to make you more comfortable, I have to say that it is not all that complicated or difficult to understand. So even if you avoided physics in high school, just be aware that it is pretty easy. Trust me.

All matter, whether it is a solid, a liquid, or gas, is made up of tiny entities called atoms. An atom is the smallest possible particle of substances called elements. An element is a chemical substance that cannot be subdivided into smaller, simpler substances. Typical elements are hydrogen, oxygen, gold, silver, copper, carbon, helium, silicon, and sodium. All matter is either an element or composed of several elements. Atoms of two or more elements often combine to form new substances called compounds. For example, water is a compound of hydrogen (H) and oxygen (O) or H_2O. Salt is a compound of sodium (Na) and chlorine (Cl) or NaCl. The smallest possible particle of a compound that exhibits all the characteristics of the substance is called a molecule.

According to the theories of physics, an atom is composed of a nucleus consisting of a core of tightly bound subatomic particles, called protons and neutrons. Protons have a positive charge. Neutrons are neutral, having neither a positive nor a negative charge.

Rotating around the nucleus are electrons. The electrons arrange themselves in multiple orbits in much the same way that the planets orbit around the sun. The orbits are sometimes referred to as rings or shells. Electrons have a negative charge. Figure 2.1 illustrates a copper atom. The number of electrons in orbit equals the number of protons in the nucleus. The number of positive charges equals the number of negative charges. Therefore, the atom is balanced electrically.

As far as electronics is concerned, the most important part of an atom is its electrons. Since electrons can be manipulated (i.e., stored or moved), they can be used to produce electricity. This electricity can then, in turn, be processed and controlled to perform a wide range of valuable functions. By applying an external force, the electrons in the outer shells can be stripped off to produce current flow.

Charge, Voltage, and Current

There are two basic types of electricity, static and dynamic. Static electricity is the buildup of a charge between two objects. Dynamic electricity supplies a continuous charge.

FIGURE 2.1 Physics model of what a copper atom looks like.

Static Electricity

With static electricity, one object has an excess of electrons and the other has a shortage of electrons. The object with an excess of electrons is therefore negative while the object with a shortage of electrons is positive. A basic law of electricity states that opposite charges attract and like charges repel. The two oppositely charged bodies, one negative and one positive, will have a high physical attraction for one another. An invisible force field called an *electric field* will exist between the two charged objects. The object with a shortage of electrons attracts the object with excess electrons.

The two oppositely charged objects will naturally attract one another. The closer they are, the greater the attraction. This attraction of the charges sets up an electrical force field between the two bodies. This electric field, like a magnetic field, contains energy that can be released to perform useful work.

Whenever there are opposite charges on two objects, we say that an electrical potential or difference of potential exists between them. This difference of potential is called *voltage*. Voltage is an electrical pressure that can cause work to be accomplished.

The charge stored on the two objects is usually called static electricity because it is stationary. However, this charge is usually dissipated in some way. If the two charged objects get too close, or the charge builds up too high, the attractive force becomes so great that the electrons jump the gap between them and create a spark. That is how lightning occurs. The clouds and the earth become oppositely charged, the earth positive, the clouds negative. The charge becomes so great that the electrons leap across the free space gap, ionizing the air and creating a path through which the electrons travel to neutralize the positive charge on the earth. The result is the massive spark or flash that we call lightning and the roar we call thunder.

In general, static electricity is not very useful. It represents energy stored as a charge, but it quickly dissipates as a spark or a brief flow of electrons between the negatively and positively charged objects when the two charged objects get close enough or when the charge gets too high. We call this an *electrostatic discharge* (ESD). Static electricity, or ESD, is regarded as more of a disadvantage or nuisance than anything else. In fact, it is one of the main causes of damage to electronic components such as transistors and integrated circuits.

Neutralizing a charge between two objects cancels or eliminates the potential. However, if we had a constant charge that could constantly be replenished, we would have a continual source of potential (voltage) and could therefore sustain a flow of electrons. With such a source of electrical energy, useful work can be accomplished.

Dynamic Electricity and Current Flow

Electricity as we know it, whether in electrical power applications or in electronics, is actually the flow of electrons. Electrons flowing from one place to another is known as current flow. And it is voltage that causes the current to flow. When electrons flow, we have energy that can be put to practical use. Electrons flowing in a filament create light. Electrons flowing in a heating coil produce heat. Electrons flowing in a motor produce mechanical energy. The object is to convert the energy from one form to another. In electronics, we precisely control the electrons with special components and circuits to produce a variety of effects.

Figure 2.2 provides a general block diagram model that shows how all electrical or electronic circuits work. A voltage source produces the energy that causes electrons to flow. This current flow is controlled or processed by a single electronic component, or many components that make up an electronic circuit. The processed electrons flow through a load that consumes or uses the electrical energy to produce a useful output. In an electrical application, the load may be a light, a heating element, or motor, as described above. In an electronic application, the load may be an antenna that radiates the radio signal produced by the electronic circuits. Or the load may be the magnetic head that develops and records digital data on a hard disk or a laser that records a video signal on a DVD.

A couple of key facts about the circuit in Figure 2.2 are required here. First, there must be a voltage source to cause the current to flow. The electrons flow from the negative terminal of the voltage source around the circuit as they are attracted by the positive terminal. Second, the circuit must always form a complete loop from plus to minus.

Current is so important that we need some way to measure it. We do this by standardizing the number of electrons that move past one point in a conductor

during a specific period of time. The charge or quantity of electrons (Q) is measured in coulombs (C). One coulomb of charge is equal to 6,242,000, 000,000,000,000 or 6.242×10^{18} electrons. If 1 coulomb moves past a point in 1 second, we say that the current is 1 ampere (A). One coulomb per second (1 C/s) equals 1 A.

Direction of Current Flow

The current flowing in electronic components and circuits consists of electrons that are influenced by a charge or voltage source. The early pioneers of electricity did not know that electricity was the movement of electrons. They knew that there was some kind of movement, of a charge or current, but they did not know what it was, or in which direction it flowed. In order to explain electrical phenomena and perform analyses of components and circuits, they simply assumed a direction of current flow that everyone agreed to and used. Their original assumption was that current flowed from positive to negative, the opposite of the actual direction. This has become known as conventional current flow.

Even after the discovery that real current was electrons moving from negative to positive, scientists and engineers continued to assume a positive-to-negative current flow. And science and engineering professors have continued to teach and support the conventional current flow concept. Most science and engineering textbooks illustrate and teach conventional current flow. Old traditions die hard, or maybe never die.

As it turns out, it does not really matter what direction current flows. Any analysis, design, or explanation can be successfully carried out using either electron flow or conventional current. One way is not any better than the other in

(*Continued*)

Direction of Current Flow (Continued)

describing or understanding electrical or electronic phenomena. Why academia has perpetuated the myth of conventional current flow rather than accepting and teaching the truth is not known. It no doubt stems from long-time heritage, custom, and convention.

Conductors, Insulators, and Semiconductors

A conductor is a material that has many electrons easily freed up by an external voltage. Current flows through conductors easily. They have what we call low resistance. Most good conductors are metals like copper, silver, or aluminum, with loosely bound electrons that can be freed by an external voltage to create current flow. Copper wire is the most commonly used conductor because of its low cost and its ability to be formed into many different shapes and sizes. Most metals are conductors but so is salt water.

Insulators are just the opposite of conductors. These are usually compounds in which the electrons are tightly bound together with the nuclei of the atoms. Even with lots of voltage applied, the electrons are hard to strip away to make current. Insulators keep current from flowing. Some common insulator materials are glass, ceramic, and plastics.

A third category of material is called *semiconductor*. It is a material that can be changed to make it a good conductor or a good insulator or anything in between. Semiconductors are used to make the transistors, diodes, and integrated circuits. The most common semiconductor is silicon. Others are germanium and carbon. Compounds such as gallium arsenide (GaAs), indium phosphide (InP), and silicon germanium (SiGe) are examples. Most integrated circuits (ICs) or chips are made of silicon.

MAGNETISM

You are probably asking, what does magnetism have to do with anything? As it turns out, it has lots to do with electricity and electronics. As you will see, the two are tied together significantly, meaning you need to know about both to get the big picture. Magnetism is essential to all electrical and electronic phenomena. Without magnetism, there would be no electricity or electronics.

Magnetic Fields

Magnetism is an invisible force that has the power to attract pieces of iron, or alloys of iron such as steel. Iron, steel, and the metals nickel and cobalt are called magnetic materials because they can be magnetized to generate a magnetic field, or they support the development and passage of a magnetic field. Magnets are pieces of such materials that exhibit this force. Magnetism has no effect on nonmagnetic materials such as other metals (aluminum, brass, etc.), or on objects made of wood, plastic, or glass.

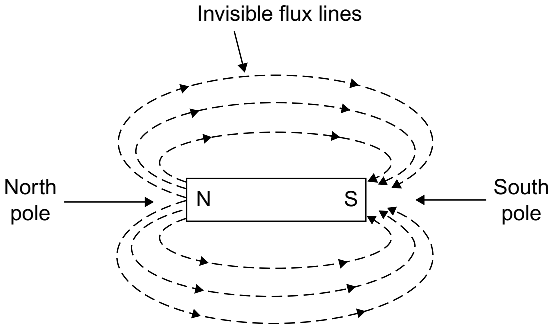

FIGURE 2.3 Permanent bar magnet illustrating the magnetic lines of flux that surround it.

You have no doubt experienced the effects of magnetism yourself. You may have played with a horseshoe magnet as a kid, or used bar magnets like the one in Figure 2.3 in a school lab. And you most likely have used flat magnets to hold paper notes on your refrigerator or file cabinet. These are called permanent magnets because they retain their magnetic force indefinitely.

A magnet is surrounded by an invisible magnetic force field made up of magnetic lines of force or flux lines. These flux lines flow out of one end of the magnet, the north (N) pole, and into the other end, the south (S) pole, as shown in Figure 2.3. The ends of the magnet are the points of the heaviest concentration of the magnetic field.

The basic law of magnetism follows: *opposite poles attract, and like poles repel.* When you get two permanent magnets together, the north and south poles will attract one another. On the other hand, two north poles will repel one another. Two south poles will also physically push away from one another. Permanent magnets are used in a variety of electrical and electronic equipment. Their most common use is in motors, where the attraction and repulsion of magnets create rotary motion.

Electromagnetism

Magnetism is also produced by electricity. Whenever electrons flow in a conductor, they produce a magnetic field. This effect is called *electromagnetism*. Figure 2.4A shows how the magnetic lines of force encircle a wire through which current is flowing. Note that the direction of the lines of force depends on the direction of the current flow.

The strength of the magnetic field around a wire depends on the magnitude of the current flowing. High current (composed of many electrons) produces a strong magnetic field. Despite the current amplitude, however, the magnetic field weakens because it spreads out quickly, even at a short distance from the wire.

If you make a coil out of the wire, as shown in Figure 2.4B, the lines of force around each turn are added together. The result is that a more powerful,

highly concentrated magnetic field is produced. In fact, the coil simulates a bar magnet with north and south poles.

As indicated earlier, the strength of the magnetic field depends on the current amplitude in the wire. High current produces a strong field. The magnetic field is also increased by coiling the wire, which helps concentrate the lines of force. The closer the turns of the wire, the stronger the field. You can also increase field strength for a given current level by simply adding more turns

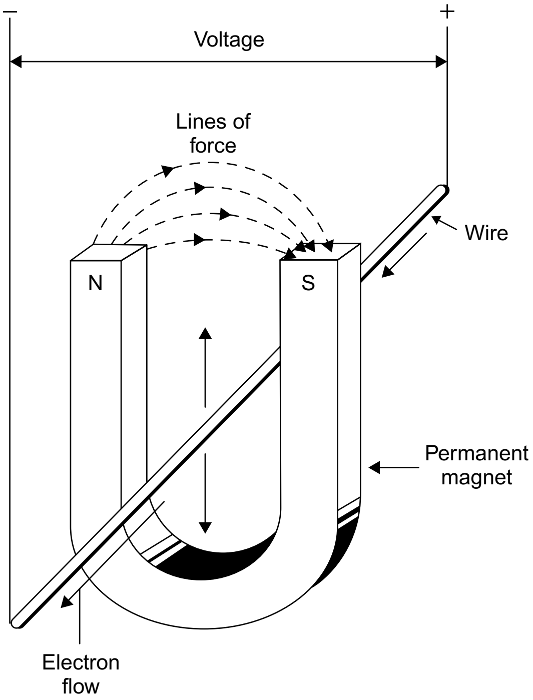

FIGURE 2.5 Relative motion between a magnetic field and a conductor such as a wire causes a voltage to be induced into the wire making it a voltage source.

to the coil. Strong electromagnets are made by tightly coiling together many turns of fine wire in several layers.

Another way to increase the strength of the magnetic field is to insert a bar or core of magnetic material inside the coil. Because flux lines flow easier in iron or steel than in air, an iron or steel bar inside the coil helps concentrate the lines of force. Most of the flux lines flow through the core because it represents a lower path of resistance than the surrounding air for the lines of force. The result is a very strong field.

Electromagnetic Induction

Another important principle of magnetism is electromagnetic induction. This principle states that whenever there is relative motion between a conductor and a magnetic field, a voltage will be induced into the conductor.

Refer to Figure 2.5. If the wire is moved up or down so that it cuts through the magnetic lines of force between the magnet poles, voltage will be induced in the wire and cause current to flow. Voltage will also be induced into the wire if the wire is held in a fixed location and the magnetic field is moved so that the flux lines cut across the wire. The wire actually becomes a voltage source. That voltage will cause current to flow. The direction of current flow in the wire depends on both the direction of the magnetic field and the direction of the relative motion between the magnetic field and the wire.

The amount of the induced voltage depends on the number of flux lines cut and the speed of cutting. The greater the number of lines of force, the higher the induced voltage and the greater the current flow. The highest induced voltage occurs when the conductor cuts across the flux lines at a right angle. If the wire moves parallel with the lines of force, no voltage is induced.

The induced voltage can also be increased by coiling the wire. More turns passing through the magnetic field will produce greater induced voltage and current flow. The motion in the magnetic field causes a small voltage to be induced into each turn of wire. All of the voltages will add together to produce a higher voltage.

In the examples above, we have assumed that the magnetic field comes from a permanent magnet. However, it doesn't really matter where the field comes from. An electromagnetic field works just as well. Electromagnetic induction is the principal method of generating electricity in the world. Most electrical power is produced by giant generators containing large coils of wire that rotate in a magnetic field. The generator or alternator in your car works the same way.

VOLTAGE SOURCES

To make current flow, we must have voltage. That voltage will produce either direct current (DC) or alternating current (AC). DC is electron flow in only one direction. AC is current that flows in one direction and then reverses and flows in the opposite direction.

DC Voltages

DC may be a fixed, steady current, one that varies, or one that switches off and on periodically. A DC voltage source is one that causes direct current to flow one way through the circuit, component, or conductor. It has positively and negatively charged terminals of a fixed polarity. It always causes electrons to flow from negative to positive.

Figure 2.6A shows a fixed, positive DC voltage source, which is usually either a battery or an electronic power supply. We call it a positive source because the negative terminal of the DC source is connected to a common point called the *ground*. The other terminal is positive with respect to ground. Voltages are always looked at or measured between two points with one point (ground) being the reference. The polarity of the voltage is the polarity of the terminal not connected to ground.

The remainder of Figure 2.6 shows graphs of DC voltage over time. In electronics we normally view DC or AC voltages with respect to time. The positive DC voltage is shown in Figure 2.6B as a horizontal dashed line.

A negative DC voltage is shown in Figure 2.6C. The dashed line representing the voltage below the zero line indicates that it is negative. The voltage is negative with respect to the reference point known as ground.

Figure 2.6D shows a varying positive DC voltage. It begins at +5 volts, rises upward to +11 volts, and then drops to +2 volts over a period of 5 seconds. The left-hand scale indicates the voltage level.

Figure 2.6E shows a pulsating DC, that is, one that turns off and on. This voltage switches on to +12 volts, stays on for 1 second, and then switches to zero for 1 second. Then this on–off cycle repeats. One cycle is the time of one ON pulse and one OFF pulse or in this case 2 seconds. Such pulse signals are usually called *binary* or *digital signals*.

AC Voltages

As its name implies, AC current flows in two directions in a conductor, component, or circuit, but not at the same time. The electrons move in one direction, then reverse and flow in the other direction, both for a short period of time. The direction of flow reverses repeatedly.

The polarity of an AC voltage reverses periodically. During one period, the terminals of the voltage source are + and −, but later reverse to − and +. This reversal continues to repeat as the voltage amplitude varies. Since it is the voltage that causes current to flow, if the polarity of the voltage changes, then naturally the direction of the electron flow will also change periodically. The electrons just flow back and forth in the circuit.

An AC voltage source is usually represented by just a circle with a varying wave inside as illustrated in Figure 2.7A. It may be the AC outlet in your home, a signal generator, or a type of electronic circuit called an *oscillator*. AC voltages and currents can assume many shapes. The most common electrical and electronic AC voltage is a sine wave, as shown in Figure 2.7B. The voltage rises gradually from zero to a positive peak, and then drops to zero. Then it reverses polarity, rises to a negative peak, and returns to zero. Each rise and fall is called an alternation. One positive and one negative alternation form a cycle. The cycles repeat over and over. The number of cycles that occur per second is called the frequency.

The AC power-line voltage that comes into your house and appears at the outlets is a sine wave. Its frequency is 60 cycles per second (cps). The term *hertz* (abbreviated Hz) is normally used instead of cps to express frequency. The power-line frequency, therefore, is 60 Hz. All radio signals are sine waves, but have very high frequencies.

AC signals can have a variety of other shapes as well. Figure 2.7C shows a square or rectangular wave. It is made up of pulses of alternating polarity voltages that switch from +6 to −6 volts. Figure 2.7D shows a triangular wave, and Figure 2.7E, a complex waveform that might represent voice or video. Regardless of their shape, AC signals have one thing in common: they reverse the polarity and direction of current flow periodically. Their frequencies can range from a fraction of a cycle per second to billions of cycles per second.

AC Frequency

Frequency is measured and expressed in units called cycles per second (cps) or Hz. Hertz is the more common unit. To express higher frequencies, the units kilohertz (kHz), megahertz (MHz), and gigahertz (GHz) are used.

1 kHz = 1000 Hz
1 MHz = 1 million Hz or 1000 kHz
1 GHz = 1 million Hz, 1 million kHz, or 1000 MHz

Table 2.1 presents a summary of various frequency ranges that you will encounter and the types of signals in those ranges.

AC Voltage Measurement

To measure or represent the amount of AC in a circuit, we usually state the peak, peak-to-peak, and root mean square (rms) values. The peak value of a wave is simply the voltage measured from the zero line to the maximum positive (or negative) value. In Figure 2.7B, the peak value of the sine wave (V_p) is 7 volts. The peak-to-peak value, normally abbreviated V_{pp}, is the positive peak added to the negative peak. Or, since the positive and negative peaks are identical in a sine wave, the peak-to-peak value is two times the peak value, or in this case 14 volts.

$$V_{pp} = 2V_p$$

TABLE 2.1 The Frequency Ranges of the Electromagnetic Spectrum and Their Applications

Frequency Range	Types of Signals
20 Hz to 20 kHz	Audio, sound, voice, and music.
300 kHz to 3 MHz (LF)	Low radio frequencies. AM broadcast.
3 MHz to 30 MHz (HF)	High-frequency radio, shortwaves. Broadcasting, amateur radio, CB.
30 MHz to 300 MHz (VHF)	Very-high radio frequencies. 2-way radio, mobile, marine, aircraft; TV and FM broadcast.
300 MHz to 3 GHz (UHF) Anything above 1 GHz is called microwave.	Ultra-high radio frequency. 2-way radio, TV broadcast, cell phones, GPS satellites, wireless broadband, wireless networks.
3 GHz to 30 GHz (EHF)	Extremely high radio frequencies. Radar, satellites, network radios.
30 GHz to 300 GHz	Super-high radio frequencies. Radar, satellites, network radios.

Another way to measure AC voltage is to use an average value known as the root mean square (rms), or effective value. The rms value is computed by multiplying the peak value by 0.707, or:

$$V_{rms} = 0.707\ V_p$$

Thus, the rms value of the sine wave is $0.707 \times 7 = 4.949$ volts. Most sine wave voltages are measured and stated in terms of the rms value. The amount of AC voltage available at a standard AC outlet, for example, is 120 volts rms. The rms value as discussed above is applied only to sine waves. The significance of the rms value is discussed later when we address power.

PRACTICAL DC AND AC VOLTAGE SOURCES

Just what is the source of DC and AC? Such voltages originate from a variety of sources.

DC Voltage Sources

Batteries

The most common source of DC voltage is a battery. A battery is a collection of cells. A cell is the basic unit of voltage generation that creates electricity by chemical action. A battery is made up of two or more cells connected together. Figure 2.8 shows the configuration of a cell. It consists of two metal electrodes immersed in a solution called an electrolyte. The chemical interaction between the metal electrodes and the electrolyte produces a separation of charges. This separation of charges results in an excess of electrons on one electrode (the − terminal of the cell) and a shortage of electrons on the other electrode (the + terminal of the cell). If a conductor is connected externally between the terminals, electrons will flow from − to +.

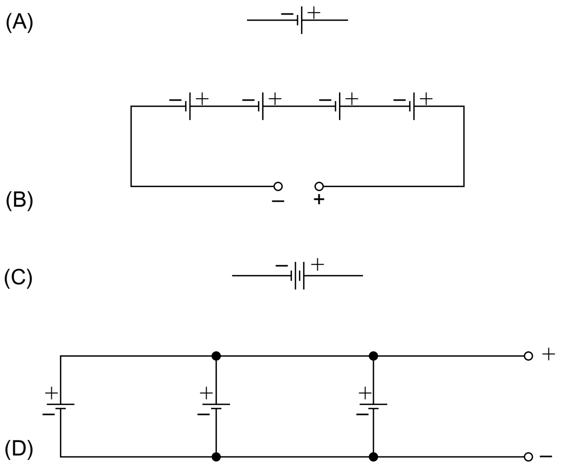

FIGURE 2.9 Battery and cell symbols used in circuit diagrams. **(A)** Cell. **(B)** Four cells in series making a battery. Cell voltage add-up. **(C)** Symbol for battery of any number of cells. **(D)** Cells in parallel to increase current capability.

The amount of voltage produced by the cell depends on the type of electrodes and the electrolyte. Various chemical combinations generate different voltages. Table 2.2 lists the most commonly used cells and the voltage they generate.

The schematic symbol of a cell is illustrated in Figure 2.9A. To create a battery, two or more cells are connected together. The cells are usually connected in series form, that is, end to end and − to +, as shown in Figure 2.9B. The cell voltages add up to produce the total battery voltage. For example, six small alkaline cells are connected in series to create a $1.5 \times 6 = 9$-volt transistor-radio battery. A car battery consists of six lead-acid cells connected in series; each produces 2.1 volts for a total battery voltage of $6 \times 2.1 = 12.6$ volts. If four nickel-metal-hydride cells are connected in series, as in Figure 2.9B, the total battery voltage is 4.8 volts.

The simplified schematic symbol for a battery is shown in Figure 2.9C. Instead of drawing all of the individual cells, the simplified battery symbol is used.

The cells listed in Table 2.2 can be separated into two categories, primary and secondary. *Primary cells* cannot be recharged. As the chemical action produces voltage, the electrodes and electrolyte are actually used up. At some point, no further chemical action is produced, and no voltage is generated. The cell must be discarded and replaced.

Secondary cells, on the other hand, can be recharged. In these cells, the chemical action can be reversed by connecting an external DC voltage to the battery. This is called *charging*. Charging forces electrons into the battery, producing a reverse chemical action that rejuvenates the electrodes and the electrolyte. The cell can be discharged and charged repeatedly, giving it a very long life.

The amount of current that can be drawn from a cell depends on its size and the quantity of the materials used. Large electrodes and electrolytes can produce more current, but the voltage stays the same; the type of material, not its volume, determines voltage.

For example, a large D-size flashlight cell and a tiny AAA penlight cell are both made of alkaline material so their output voltages are both 1.5 volts. The D-cell, however, can produce more current and will have a longer life because it is larger.

A greater current capacity can be obtained by simply connecting two or more cells in parallel. In a parallel connection, the cells are wired across one another, all + leads connected together, and all − leads connected together, as shown in Figure 2.9D. The output voltage remains the same, but the current output can be higher.

Solar Cells

A special type of voltage-producing cell is the so-called *solar cell*. Also called a *photovoltaic* (PV) cell, a solar cell converts light into electrical energy. When the sun or artificial light shines on the cell surface, a voltage is generated. The most commonly used material is silicon, and a typical cell generates about 0.5 volt. Other materials, such as cadmium sulfide and gallium arsenide, are also used.

You have probably seen solar cells used in hand-held calculators. Big arrays of solar cells are now being adopted as an energy source for homes and businesses. Another important application is spacecraft. Virtually every satellite, deep-space probe, or other space vehicle, uses solar cells for power. Huge panels of solar cells connected in a complex series–parallel array produce a powerful battery that can operate all electrical and electronic equipment on board. Typically, however, such a solar battery is primarily used to recharge the main spacecraft power source, which may be a nickel-cadmium secondary battery, as shown in Figure 2.10. The voltage produced by this array is 2 volts.

Fuel Cell

A fuel cell is a special type of battery that combines oxygen and hydrogen gas to produce voltage and electron flow. That means you have to have a supply of hydrogen gas, which is usually stored in a bottle or other container. Typically, the oxygen can be extracted from the air, but if not you will need a bottle of oxygen as well. When you combine the two, charges separate and plus and minus terminals are formed. Most fuel cells generate between 0.5 volt and 0.9 volt, so you have to put many of them in series to be useful. Usually they are bulky and inconvenient because of the need for the gases. But as long as oxygen and hydrogen are supplied, the fuel cell produces the voltage. Heat and water are by-products of the chemical process, making them essentially impractical for many applications.

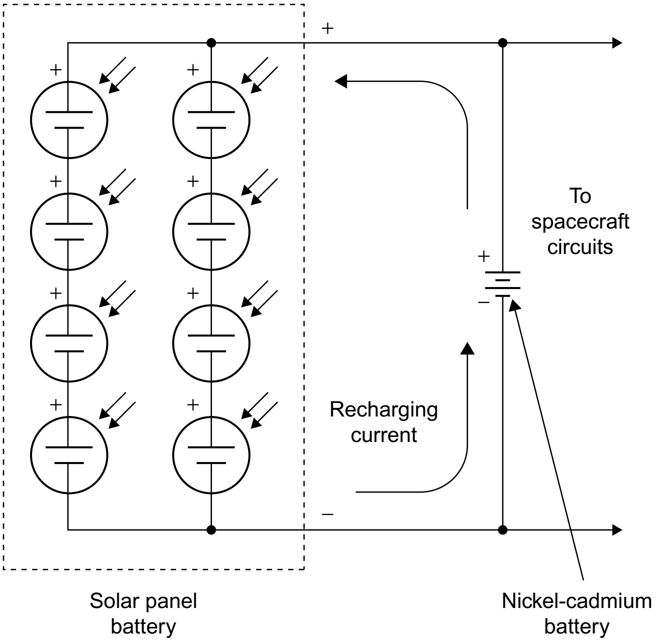

FIGURE 2.10 Panel comprised of solar cells in series and parallel make up DC source that charges the battery in a spacecraft.

Power Supplies

Electronic circuits require a source of DC for proper operation. A great many electronic products are still powered by batteries because they are small and portable, such as cell phones, iPods, and the like. Other electronic equipment is designed to operate from the AC power line. Such equipment contains an electronic power supply that converts AC into the required DC voltages. Computers, TV sets, and other nonportable electronic equipment have an AC power supply.

AC Voltage Sources

Generators

The AC that appears at the outlets of our homes and offices is produced by huge electromechanical generators owned and operated by an electrical utility company. A source of mechanical power—such as water, or a steam turbine powered by oil, coal, or nuclear fuel—operates the generator. The turbine converts steam into mechanical energy to turn the generator. The generator rotates coils in a strong magnetic field to produce a voltage. The speed of rotation of the coils determines the frequency. That voltage is a 60-Hz sine wave.

The big wind generators popping up across the landscape also produce AC sine waves, but because the rotational speed depends on the wind speed, the AC frequency will vary, which is unacceptable. Therefore, the AC voltage they produce is converted to DC, and then back into AC of the correct frequency (60 Hz) to be used or put on the AC power grid.

Another example is the alternator in your car. "Alternator" is just another word for an AC generator. The alternator, driven by the car engine through a belt, produces AC output that is converted to DC by diodes making up a rectifier. The rectifier output is DC to charge the battery.

Inverters

Electronic circuits called inverters are used to produce AC from a DC source. This is common in solar power systems. The solar cells produce DC, which keeps batteries charged. The DC is then converted to AC by the inverter.

In electronic equipment, AC signals are generated by circuits called *oscillators* or *function generators*. The AC signals are sine waves, square (rectangular) waves, or triangular waves, among others.

Analog and Digital Signals

You have no doubt heard the terms "analog" and "digital." These terms distinguish between the two main types of voltages or signals in electronic equipment. Analog signals are voltages that vary smoothly and continuously over time. You saw some in previous figures. Analog signals may be either DC or

AC. A continuous DC voltage is analog, as well as a varying DC signal. A sine wave and the random signal in Figure 2.7E are also analog signals.

Analog signals come from microphones, video cameras, and sensors that detect light level, temperature, and other physical conditions. The most common types of analog signals are voice or music from a microphone and video from a camera.

Digital signals are pulses or on–off signals. The DC pulses in Figure 2.6E and 2.7C are digital. Most digital signals are binary in nature, meaning they only have two voltage values. In Figure 2.6E the two values of voltage are +12 and zero volts. In Figure 2.7C the two voltage levels are +3 and −3 volts.

You will see both analog and digital signals in all sectors of electronics. Today, most signals are digital. Special circuits called analog-to-digital converters (ADC) and digital-to-analog converters (DAC) are used to translate between the two types of signals.

Fourier Theory and the Frequency Domain

We normally think of electronic signals as voltages that vary over time. Waveforms showing signals are said to be in the time domain. Time is the horizontal axis in a graph. But there is another way to look at signals in the frequency domain where frequency is on the horizontal axis. For example, a sine wave is shown as a single vertical line at its frequency as Figure 2.11A shows. The height of the line is representative of the voltage level, either peak or rms.

The big question is, how do you show a complex signal like a square wave in the frequency domain? The only way to do this is to use the Fourier theory that says that any complex nonsinusoidal wave is made up of a group of sine waves added together. There is a fundamental sine wave that occurs at the signal frequency plus harmonic sine waves. A harmonic is a sine wave whose frequency is an integer (whole number) multiple of the fundamental sine wave. The second harmonic of a 50-MHz sine wave is a 100-MHz sine wave. The third harmonic is a 150-MHz sine wave and so on. If you add the fundamental sine wave to multiple harmonics of differing amplitudes and phases, you can create any shape of wave.

For instance, a square wave is made up of a fundamental sine wave and all the odd harmonics. A 1-MHz square wave is made up of a fundamental 1-MHz sine wave and harmonics of 3 MHz, 5 MHz, 7 MHz, and so on. According to Fourier theory, it takes an infinite number of harmonics but in reality only a few (like up to the fifth or seventh) are needed to approximate the square wave. The frequency domain plot of a square wave therefore would look like the one in Figure 2.11B.

When looking at a time domain view of a signal, try to keep a frequency-domain picture in mind at the same time. You cannot actually see the third or fifth harmonics in the time domain plot but they are buried in there just the same.

Getting Familiar with a Multimeter

One of the things you are going to need as you work with electronic parts, circuits, and equipment is a multimeter. This is a test instrument that measures voltage, current, and resistance. Some also measure capacitance and other things. These multimeters are usually hand held and battery operated. There are two basic types, analog and digital. Analog meters use a dial to show the measured value. Digital multimeters (DMMs) have a liquid crystal display (LCD) to show the measurement. See Figure 2.12. The two types work equally well; which one you use is typically a matter of preference for meters versus digital displays. I recommend a digital unit.

The good news is that multimeters are not expensive. You can get one for as little as $10, but a better unit may cost you several times that. The cheaper units are kits that you will need to build yourself. I do not recommend a kit if you are just starting out. Later in this book I will discuss kits in more detail. In any case, you need to buy a multimeter and learn to use it. Plan to buy one as soon as you can. Check your local Radio Shack store or buy online.

Three good sources of multimeters by mail order or web order follow:

Hardware Sources

As an electronic experimenter, you should be familiar with buying parts and equipment. Radio Shack stores still stock some parts but today most hobbyists and experimenters buy via the mail or online. The most popular sources of parts and equipment are All Electronics, Digi-Key, and Jameco. And you will discover others. You can go to their websites, but you really should get on their mailing list and get a catalog. Do that as soon as you can. Links to these sources follow. You can get your multimeter from one of them as well.

Magazines of Interest

As you are learning electronics, you need to be continuously aware of what is going on in the industry and with the technology. Magazines are a good source of that information. One that you should read on a regular basis is *Nuts & Volts*. It is

available at some newsstands and bookstores, but if you cannot locate it, go to the website and subscribe. This magazine has lots of articles and columns, including construction projects. It is a great way to stay up to date and learn more. *Nuts & Volts* also publishes *Servo* magazine, which is aimed at people who like to build and play around with robots.

Another recommended magazine that has an embedded controller emphasis is *Circuit Cellar*. This publication contains great educational articles and projects. Get a subscription if you are serious about learning more.

Another interesting magazine is called *Make*—it is not strictly electronics but it usually contains some good electronic projects. It also features other mechanical projects such as robots, among other things. This one is definitely worth a look the next time you are at the newsstand.

Project 2.4

Measuring Voltages

A good first step in using a multimeter is to measure voltages. Batteries are a good place to start. Look around the house and locate some batteries that you commonly use. Take them out of the equipment before you measure them. You will most likely find AA or C cells. Set the multimeter to measure DC according to the meter user's manual and connect the test leads to the battery. The red lead is +, the black lead is −. The LCD on the meter should show the voltage. It should be 1.5 volts. You can also check batteries in some cordless phones, cell phones, or other devices. You may be able to remove the battery from a laptop. In each case, check to determine the battery technology—lithium ion, alkaline, and so on.

Two key points to remember. First, if you get the test leads reversed, the red to the − terminal of the battery and the black to the + terminal, the meter will read a negative value. That just means that the leads are reversed, nothing more. Second, you cannot typically judge the condition of the battery by measuring its voltage. With no load on the battery, no current is drawn from it so you are just measuring the characteristic voltage. If you connect the battery to something, current will flow and its voltage will decrease slightly. If it decreases a lot, the battery is going bad. If the cell or battery voltage is several tenths of a volt lower than the characteristic value given in Table 2.2, the battery is probably bad.

You could also go out to your car and measure its battery voltage. Be careful. You cannot get shocked but you could short something. When the engine is off, the battery will probably register about 12 volts. With the engine running, the battery voltage will be a bit higher, as much as 15 volts or so. The generator is charging the battery, making its voltage a bit higher.

(*Continued*)

Project 2.4 (Continued)

One last thing: you can use the multimeter to measure the AC line voltage at an outlet. Only do this if you have probes that will fit into the slots on the outlet.

And be super careful as you can kill yourself. Be paranoid, even.

Set the multimeter for AC voltage at an appropriate level of at least 120 volts, according to the multimeter manual. Place the probe tips into the AC outlet and read the voltage.

Do NOT touch any metal with the probe tips!!

Your value will depend on things like how far you are from the power station, what appliances and other items are on, and time of day. In any case, the voltage range is about 95 to 130 volts. It is rarely lower than 110 or higher than 125 volts. The typical value is 120 volts, or what is called *nominal*. I measured mine at 117 volts.

Chapter 3

The Systems versus Components View of Electronics

A Fresh New Way to Learn about Electronics

In this Chapter:

- Systems defined.
- Examples of systems.
- Introduction to basic electronic components.

INTRODUCTION

When learning about electronics in the past, you started with basics of physics and math, and then went on to learn electrical theories. Next came instruction in how electronic components work, and then you combined them into circuits. Then you put the circuits together into specific pieces of equipment. Finally, at last, knowing the equipment, you could understand the application, such as TV or computers or audio or home system control or whatever. This approach to learning is called the bottom-up approach. You learned the details and added them all together to get to what you really wanted to know about—the application and its technology.

That is still the way you learn electronics in college today, and it is the approach taken by most other electronics books you may have seen. This book doesn't take that old legacy path. Instead it skips most of the early background and theory, goes right for details on the circuits, and then builds to the applications. It is a much more interesting way to learn electronics. And it is also far more relevant to how electronic equipment is implemented today. We call this way of learning the "systems view" of electronics.

WHY SYSTEMS AND NOT CIRCUITS?

What is the advantage of this approach? First, thanks to modern semiconductor technology, most electronic components and circuits are inside chips or integrated circuits (ICs). You can't see them, and you can't access, test, or replace

© 2010 Elsevier Inc. All rights reserved.
doi: 10.1016/B978-1-85617-700-9.00003-5

them. About all you can do is learn what they do, and then work with the various input and output signals. Since you do not have access to the components and circuits, there is some argument as to why you need to learn all that circuit theory detail. If you are an engineer designing ICs, you definitely need to know this. Otherwise, it is just a waste of time unless you want to know just for the heck of it. Some of it is nice to know, of course, but in most cases it is not necessary. What you really need to know is what the circuit is, what it does, what its characteristics are, and what the inputs and outputs should look like.

A good example is the power supply in a PC. If it goes bad, you just replace it with a $30 unit that you can buy online. Troubleshooting the power supply would take many hours and require some expensive test equipment and access to spare parts. The whole repair could take hours and at a typical rate of, say, $50/hour, or more, it could cost hundreds of dollars and take weeks to get the new parts. A quick replacement with the $30 unit takes only about a half hour at most. So for less time and money, you get your PC working faster. Not a bad deal at all.

A cell phone is the same. It takes hours of troubleshooting and very expensive test equipment to troubleshoot and repair one. A typical repair would cost hundreds of dollars. Consequently, it is rarely done. It is cheaper to get a new cell phone, and it will be a better one at that. And it may even be free if you renew your service contract. That’s electronics today.

The ability to analyze circuit operation by tracing electron flow through the various components used to be necessary. That made it necessary to know about all the components in detail and how they all come together to make a circuit. But with the systems view, you rarely need this knowledge unless you are an engineer designing the circuits or the equipment. In most cases you are not, so why invest the time?

The systems view is a better approach, as you do learn about the circuits and the equipment at a higher level. Later, if you want or need to, you can delve deeper into the circuit and component details, just for fun or to satisfy your curiosity. We won’t do that in this book. But you will get the system view and big picture that will serve you well in learning electronics.

The systems view is more important today because ICs have made it possible to largely ignore the internal details. The ICs and systems on a chip (SoC) have resulted in the throw-away electronics society in which we live. It is no longer possible or economical to repair most electronic equipment thanks to ICs. The cost of labor, the cost of test instruments to troubleshoot equipment, and the difficulty of replacing ICs has made it more practical to just discard a bad piece of electronic equipment rather than repair it. It costs less and you get a newer and better replacement product as a result. Not a bad deal.

Yes, it is still possible to repair some equipment. For example, big expensive equipment such as a magnetic resonance imaging (MRI) machine is usually repairable, but it is done by replacing not bad components, but by replacing defective modules, subassemblies, or printed circuit boards.

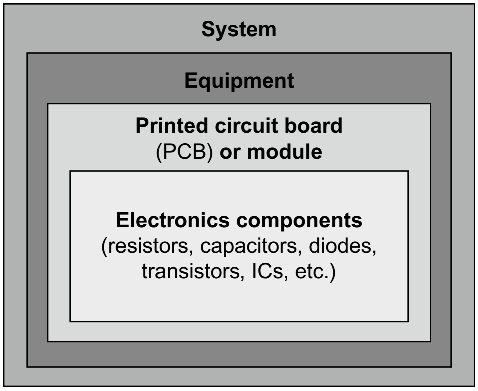

FIGURE 3.1 Hierarchy of electronics from systems to components.

You don't have to know how to analyze circuits to do that. You just troubleshoot by observing signal flow, measuring inputs and outputs, and replacing any module or subassembly that does not work. You get the equipment working sooner and at lower cost.

A good way to picture the systems view is shown in Figure 3.1. It all begins with the components that make up the circuits that in turn make up the modules and subassemblies, usually on printed circuit boards (PCBs). Those are put together to form pieces of equipment. Finally, multiple pieces of equipment may end up being interconnected to form some kind of system. A few system examples will show you the idea.

A personal computer (PC) is a great example of a system (see Figure 3.2). It is made up of modules including a mother board with its processor, memory ICs, and input/output (I/O) interfaces. There is a power supply module, a hard disk drive, a CD/DVD drive, and perhaps a video card. Then the system is completed when it is connected to the video monitor, keyboard, printer, and Internet modem.

A consumer home entertainment system is made up of a big screen HDTV set, a cable or satellite box, a DVD/Blu-ray player, and an audio amplifier/receiver with speakers. Other equipment may be involved. The TV itself or any of the other components are systems in their own right.

An iPod or MP3 player is a simple system. Shown in Figure 3.3, it consists of a memory, either a tiny hard disk drive or a solid-state flash memory that stores the music, an audio codec IC that does the digital music decompression, digital-to-analog conversion and analog-to-digital conversion for storing music, a microcontroller that controls the whole thing including the selection controls, and the LCD readout. A pair of audio amplifiers and a headset complete the system. A power management system charges the battery and doles out DC to power the various ICs.

An MRI machine is a whole system. It is made up of the central bed surrounded by a superconducting magnet and radio frequency–sensing coils, high-power radio frequency (RF) amplifiers and detectors, the video imaging section, and a computer that runs the whole thing.

Anyway, you get the picture. There are big systems, little systems, and lots of in-between systems. Their main characteristic today is that you cannot get at the individual components and circuits, but there are exceptions.

In this book we look mainly at the circuits, equipment, and systems, not the components. We will give you a quickie introduction to the main components but move on to the circuits and systems.

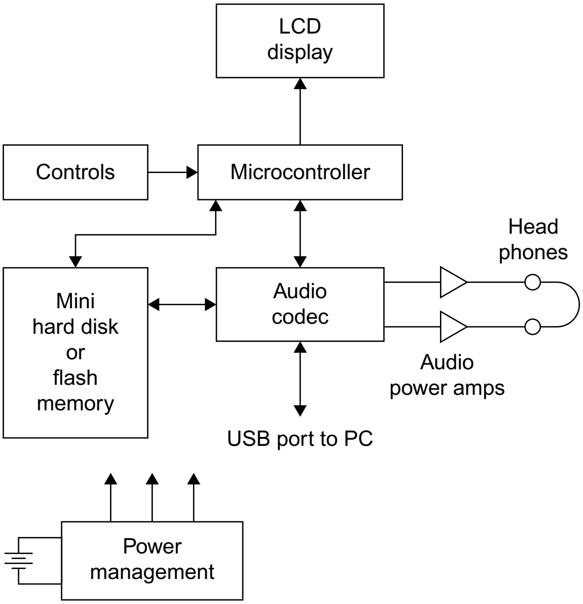

FIGURE 3.3 System block diagram of iPod or MP3 music player.

ELECTRONIC COMPONENTS

Most systems today are collections of ICs wired together on printed circuit boards and packaged in a housing of some sort. The MP3 player/iPod in Figure 3.3 is a great example. Each block in that diagram is an IC. In the past, systems were made with PCBs and other assemblies, but the circuits were made with discrete components, individual resistors, capacitors, diodes, transistors, and even some ICs. You will still see these here and there in modern equipment; just remember that most circuits and equipment are just a batch of ICs.

Just so you won't be ignorant of components, here is a nutshell introduction that should serve you well when learning electronics the system way. If you want to dig deeper, you can find many other books that will make your eyes glaze over with detail.

Switches

There is no simpler electrical component than a switch. It is just two (sometimes more) metal contacts and a mechanical device to open and close them. In one position the switch contacts are open and not touching so that no current will flow through them; the switch is "off." Moving the switch lever, the contacts are made to touch making a path for current to flow; the switch is said to be "on."

Switch closed or on

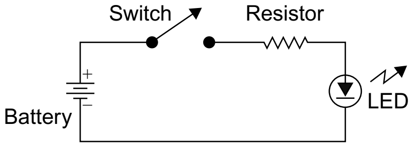

FIGURE 3.4 Switch and how it is used.

Figure 3.4 shows a switch in a circuit diagram called a *schematic*. This shows the switch connected to a battery and a light-emitting diode (LED) in a simple flashlight. The other component is a resistor to limit the current.

Resistors

Resistors are one of the most common components in electronics. These devices offer opposition to current flow; they limit or set the level of current in a circuit. The opposition to current flow is measured in ohms. The higher the ohms value, the more resistance it offers to electron flow.

Ohm's Law

There is one key electrical relationship you should know, called Ohm's law. It is simple and easy to understand. It says: The current in a circuit (I) is directly proportional to the voltage (V) and inversely to the resistance (R). It is usually expressed as a simple formula:

$$I = V/R$$

If you increase the voltage in a given resistance, the current increases. That makes sense since the voltage charge simply attracts and repels more electrons. Increasing the resistance makes the current decrease. Since resistance opposes current flow, more resistance with the same voltage will make the current decrease.

Keep this simple relationship in mind, as it is the heart of every electrical and electronic application.

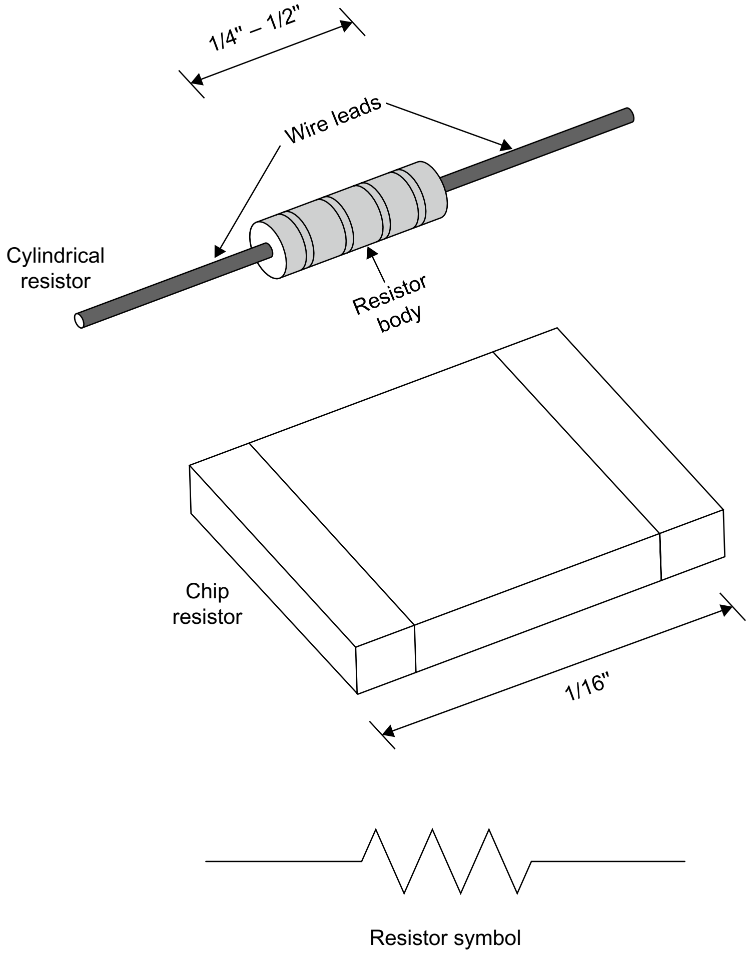

FIGURE 3.5 Types of resistors and schematic symbol.

Today most resistors are made along with all the other circuitry in an IC. But discrete component resistors are also still fairly widely used. The most common ones are called chip resistors and look something like the one shown in Figure 3.5. They are small and you can just make them out when looking at a printed circuit board. Older but still used resistors are cylindrical like the one shown in Figure 3.5. The schematic symbol used to represent a resistor in a schematic diagram is shown in Figure 3.5. Color-coded resistors use a set of color bands with a special code to indicate their value (see Figure 3.6).

An example of a common resistor circuit is the voltage divider shown in Figure 3.7. It is used to attenuate a voltage or signal or make it lower. The two resistors of the voltage divider are connected in series. When current flows, a

voltage develops across the two resistors. The input voltage is divided between the two resistors according to their value. In any case, the output is taken from one of the resistors and it is lower in value than the input.

Capacitors

A capacitor is a device that stores an electrical charge. It is made up of two metallic plates separated by an insulator such as plastic or ceramic or even air (see Figure 3.8). The symbol for a capacitor in schematics is also shown.

The basic function of a capacitor is to be charged or discharged. You charge the capacitor by applying a voltage to it as shown in Figure 3.9A. The electrons pile

up on one plate making it negative and are pulled away from the other plate making it positive. It takes a finite amount of time for the capacitor to charge as determined by the values of capacitance (C), stated in farads (F), and resistance (R). That time is called the time constant (T). In the charged state, the capacitor stores the voltage. The capacitor in its charged state is almost like a battery, as it can supply DC voltage to a circuit or load.

The energy stored in the capacitor is used by discharging it into a load such as a resistor (see Figure 3.9B). The electrons then flow from the negative plate through the resistor to the positive plate. Current flows until the charge is dissipated. Again, it takes time for the discharge to occur.

When capacitors are used with AC signals, they offer opposition to current flow called *capacitive reactance*. It is like resistance in that it determines current flow, but it varies with the frequency of the AC and capacitor value.

Capacitors perform all sorts of functions in electronic circuits. They are used for filtering and they are used to pass AC but block DC. Figure 3.10 shows a low-pass filter comprised of a resistor and a capacitor. This is a frequency-sensitive circuit that passes AC signals below a specific frequency called the *cut-off frequency* (f_{co}) and attenuates the frequencies above the cut-off. Figure 3.11 shows how a capacitor passes AC but blocks DC.

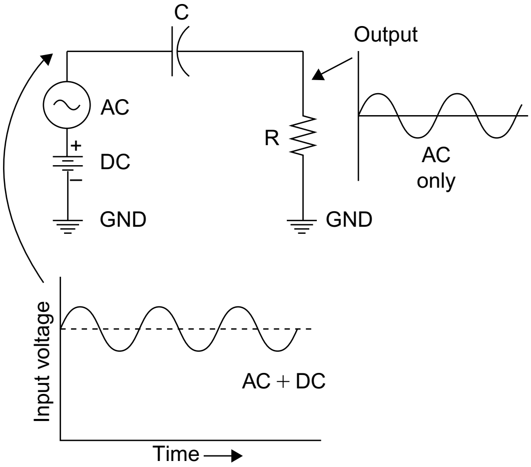

FIGURE 3.11 How capacitor passes AC sine wave but blocks DC voltage.

A Word about Ground

In schematic diagrams like Figure 3.10, you will see the triangular-shaped symbol labeled GND. This means ground. Ground is an electronic term that refers to a common connecting point. It may be a common wire, a metal chassis, a copper area on a printed circuit board, or some other conductive part or area. In this figure, it means that the bottom of the AC generator and the bottom of the capacitor are connected together.

Ground is also the common reference point for measuring all voltages.

Inductors

Inductors are mainly just coils of wire. When current flows through them, they produce a magnetic field and induce a voltage in themselves. This is called *self-induction*. The induced voltage has an opposite polarity of the applied voltage. The result is that the induced voltage causes opposition to the current flow. We often use that characteristic to control current flow in AC circuits. Like the capacitor, the inductor is an opposition to AC called *inductive reactance*. Figure 3.12 shows the symbol of an inductor as used in schematic diagrams.

Transformers

A transformer is usually comprised of two coils or windings on a common core. The schematic symbol is shown in Figure 3.13. A voltage applied to one winding called the *primary* causes current to flow and a magnetic field to develop. This magnetic field spreads out and induces voltage in the other

winding called the *secondary*, thereby transferring electrical energy for one coil to another by way of the magnetic field. Transformers are used to step up or step down voltage levels of AC signals. They are also used for signal isolation as well as impedance matching.

Diodes

A diode is a semiconductor component that lets current flow through it in one direction but blocks current in the other direction depending on the polarity of the voltage applied to it. It acts like a polarity-sensitive switch. Figure 3.14 shows a typical diode, the diode schematic symbol, and how it is biased for current or no current.

Diodes are used mainly for rectification, the process of converting AC into DC. Figure 3.15 shows how a diode converts an AC sine wave into DC pulses. If you put a capacitor across the load resistor, it will charge up to the peak sine voltage and store it. The result is that the output is a near-constant DC value. Most electronic power supplies work like this.

Special diodes are made to emit light (LED), regulate voltage (zener diode), act as a variable capacitor (varactor), or perform as a switch (PIN diode).

Transistors

A transistor is a three-terminal semiconductor device that uses a small input signal to control a much larger output signal. One type of transistor is the bipolar junction transistor (BJT) shown in Figure 3.16. A small current applied to the base element is used to control a larger current flowing from emitter to collector.

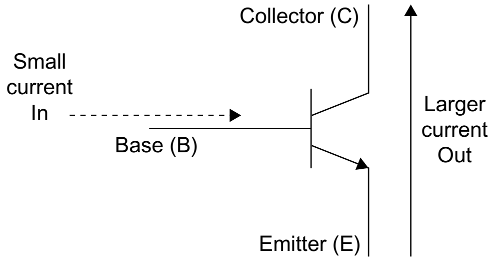

FIGURE 3.16 Schematic symbol for bipolar junction transistor (BJT) and its inputs and outputs.

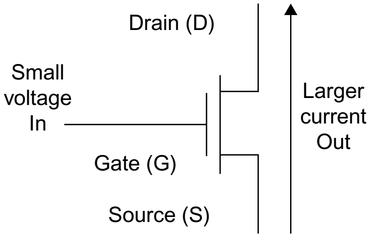

FIGURE 3.17 Schematic symbol for MOSFET and its input and outputs.

Another type of transistor is the metal oxide semiconductor-field-effect transistor (MOSFET). It too has three elements, as shown in Figure 3.17. A small voltage on the gate controls a larger current flowing from source to drain.

Transistors have two basic functions: amplification and switching. In amplification, the small input variation causes larger output current variation. The small input signal isn't really made bigger, but the larger output variation has the same shape and characteristics, resulting in the same effect. The transistor simply varies the larger DC current from the supply and shapes it like the input.

Amplifiers

Figure 3.18 shows a simple BJT amplifier. The base resistor sets the base current turning the transistor on so that current flows from emitter to collector. Its output voltage is a DC value at about half the supply voltage. Now, if a small AC signal is applied through the capacitor as shown, the base current will vary. This will vary the collector current and the voltage across the collector resistor. A small variation in the base current produces a larger variation in the collector current. The output voltage is an enlarged version of the input, except that it is reversed in phase. We say that the output is 180 degrees out of phase with the input, called *phase inversion*. The output is a DC signal, but to convert it to AC we pass it through a capacitor to the load. All amplifiers generally work like this.

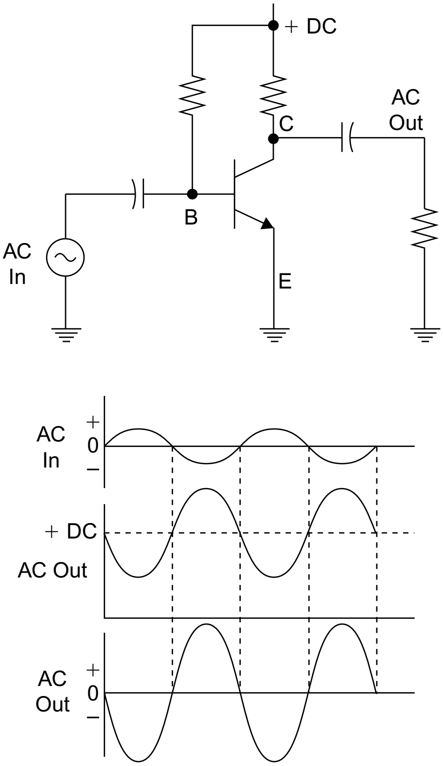

FIGURE 3.18 Simple BJT amplifier and how it works.

Switches

As a switch, the transistor output current is turned off or on by the smaller input current or voltage. A small input signal can switch a larger output current off and on. Switching transistors can switch very fast (in less than nanoseconds). Figure 3.19 shows a MOSFET switch. If the input voltage on the gate is zero, the MOSFET does not conduct. It acts like an open or off switch. The output then is just the supply voltage (+V) as seen through the resistor.

Now, if we apply voltage to the gate above a certain threshold level, the MOSFET will conduct. It acts like a closed or on switch so current flows in the resistor. The output is a very small value near zero. Figure 3.19 also shows what the inputs and outputs look like with a square wave applied.

Integrated Circuits

An IC is also called a chip. It is a complete circuit made on a single chip of silicon. All the components are made at the same time and interconnected to form an amplifier, microcomputer, memory, oscillator, radio transceiver, or

whatever the function. The IC is then connected to DC power and it works. All you do is apply the inputs, and new outputs are produced according to what the IC function is. Most circuits today are ICs.

There are all sizes and types of ICs. There are linear circuits for analog signals, digital circuits for binary signals, and mixed signal IC for both analog and digital signals. There are small ICs that are just an amplifier or logic circuit. Then there are even larger circuits like a computer memory or a microprocessor that is the heart of every computer. Finally, there are complete systems on a chip (SoC). Each year, it is possible to make the components on a silicon chip smaller so you can put more on a chip economically. That is why we have iPods, cell phones, and other really small devices that in the past would have been huge pieces of equipment. Figure 3.20 is representative of ICs today.

There are lots of other electronic components but these are the main ones. A few others are introduced in later chapters.

While this book attempts to get you thinking about the big picture—the systems rather than the individual components—we cannot ignore discrete components completely. Well, actually we can, but you may be curious and want to have a bit more involvement with them. If so, the projects to follow will show you how individual parts are used. The circuits presented here are trivial compared with the sophisticated technology you use every day, such as big-screen LCD HDTV sets, laptops, cell phones, and your wireless Internet broadband router. Feel free to skip these if you wish.

Project 3.1

Setting Up a Simple Lab

If you want to play around with some components just to get the feel for how it used to be, you need to set up a simple lab. If you performed the previous projects, you already have a multimeter. Now you will need a way to interconnect parts in circuits and a power source.

The power source can be four AA cells in a holder. This will provide DC voltage to power the circuits. Or you can use a common 9-volt battery. A battery clip with leads will allow you to connect the battery to the circuit.

Next you will need a breadboard. This is a connector socket with multiple holes in it like that shown in Figure 3.21. You plug the wire leads of the components into the holes to connect them to one another without soldering them.

Then you will need some components such as resistors, capacitors, and transistors. In this project, the goal is to get the battery and the breadboarding socket. The remaining projects for this chapter are circuit experiments.

You can get the breadboard from a local Radio Shack or from a mail order house like Jameco. There are usually two sizes, large and small. The small one is adequate. Figure 3.21 shows a larger one.

Get a battery holder that will take four AA batteries. Again, Radio Shack or Jameco are good sources. Some battery holders also have an on/off switch but it is not necessary. They will have two leads for connecting the battery to the circuit. The 9-volt battery clip is shown in the figure.

Once you get the parts, put the AA cells into the holder so that you connect the negative end (−) of one battery to the positive end (+) of the next so that the cells will be in series. That way their voltages will add together. The circuit should look like that in Figure 3.22.

Next, test the battery. Using your multimeter on the DC ranges, and measure the voltage across the battery holder wires. What do you get? You should read 6 volts or a bit more. The 9-volt battery should, of course, measure 9 volts.

Now you are ready for a few additional component projects.

Now, wire up the circuit in Figure 3.23. A pictorial is shown in the figure as well. Be sure to get the LED leads connected correctly, for if not, you will zap it. See the wiring details in the figure.

The resistor is needed to control or limit the current so that you do not blow out the LED. A value of 220 ohms is a good one if you use the 6-volt battery. The color code for that resistor is red-red-brown-gold. If you are using the 9-volt battery, use a 330-ohm resistor (orange-orange-brown-gold).

Wire the circuit and connect the battery. The LED should light. Now you are an electronic circuit genius.

Project 3.3

Capacitors

Capacitors store a charge and then release it. The charge is stored energy. You charge the capacitor by applying a voltage to it. Then you discharge the capacitor by connecting it to a load like a resistor. This brief project will illustrate that idea.

You will need the following parts from Radio Shack or another source. Get a 100-K ohm resistor (color code brown-black-yellow-gold) and a 100-μF (microfarad) electrolytic capacitor. This capacitor is polarized, meaning that you have to observe the polarity of the voltage applied to it. The wire leads are usually marked with either a + sign, or sometimes with a − sign.

Wire the circuit shown in Figure 3.24 on the breadboarding socket. Do not initially connect the positive lead of the battery to the resistor. Connect your multimeter across the capacitor. Now connect the 6 volts (or 9 volts) from the battery supply as indicated when you are ready to start charging the capacitor. You should see the voltage begin to rise slowly. It should take about 50 seconds for the capacitor to fully charge to 6 (or 9) volts.

Now disconnect the battery's positive lead. The capacitor retains the charge, as you should see on the meter. It will probably begin to drop slowly as it discharges into the meter.

Now use the capacitor as a voltage source. Connect the capacitor to the resistor and LED you used earlier as shown in Figure 3.24. The capacitor will discharge quickly and you should only see the LED blink briefly. To see it again, recharge the capacitor and repeat.

Transistor Switch

A transistor makes a good switch, especially a MOSFET. And it is easy to use. This project demonstrates how the MOSFET can be used to turn the LED off and on.

Acquire a MOSFET, such as the IRF510 or its equivalent. Then build the circuit shown in Figure 3.25. Be sure to follow the guidelines for wiring the transistor. Use the LED and 220- (or 330-) ohm resistor that you used before.

Now, connect the battery. Touch the wire from the gate on the MOSFET to the +6 volt or +9 connection like on the resistor. This will turn the transistor on and it will act as a switch to turn on the LED. Disconnect the gate from +6 volts and the transistor switch goes off, turning off the LED.

Chapter 4

Electronic Circuits: Linear/Analog

The Building Blocks of Electronic Equipment

In this Chapter:

- Linear circuits defined.
- Types of linear circuits.
- Characteristics and specifications of the most common linear circuits.

INTRODUCTION

The basic building blocks of electronic equipment are individual circuits made up of transistors, resistors, capacitors, and sometimes transformers, inductors or other components. It used to be that circuits were made up of individual discrete components that were wired together on a printed circuit board. But today, most electronic circuits are in integrated circuit (IC) form or more likely multiple circuits are already combined on a single silicon chip to create a larger circuit, sub-system or system on a chip (SoC).

While most circuits are ICs there are still some cases where discrete components are necessary or desirable. The most common examples are high voltage or high power circuits that would burn up a tiny silicon chip. Discrete components have not gone away entirely and you will find some of them external to an IC such as larger capacitors or inductors that just cannot be easily integrated onto a chip or transistors that can handle higher voltage or power. As mentioned before, we are not going to talk about the make-up or operation of individual circuits, Instead, this book treats circuits as just building blocks with an input and an output that process the input in some way to create a new, different output.

LINEAR CIRCUITS

There are two basic types of circuits, linear and digital. Digital circuits are covered in the next chapter. Linear circuits are those circuits that process analog signals. Recall that analog signals are those that vary smoothly and continuously

over time in contrast to pulse and digital signals that are voltages that switch off and on very fast. Analog signals are like sine waves, voice signals, video signals, radio waves, and voltages from sensors like a temperature transducer. DC, either a constant value of voltage or one that is varying, is also an analog signal.

A linear circuit is one whose output is proportional to its input. See Figure 4.1. Its so-called response is a straight line or what a mathematician would call a linear function. The best example of this is the amplifier where its output is proportional to its input so that it accurately reproduces the input faithfully but at a higher voltage or power level. In the figure, with 0.4 volt input you get 4 volt output. That means the amplifier has a gain of 10. Linear circuits do not distort the signal. This chapter covers linear circuits with most of the emphasis on amplifiers since that is the largest category of linear circuits. And as it turns out, most other types of linear circuits are just amplifiers connected in different ways to give different processing results.

Amplifiers

The basic block diagram symbol for an amplifier is a triangle. See Figure 4.2. It has an input and an output. Amplifiers also have one or more DC inputs as well. This DC from a battery or other power supply is what powers the circuit

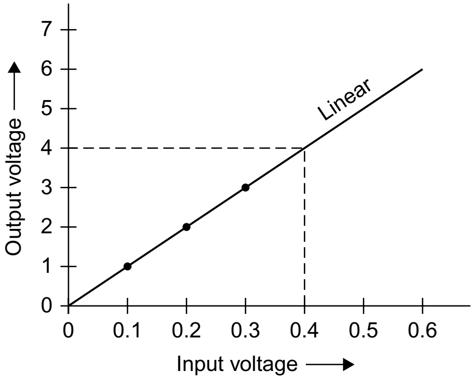

FIGURE 4.1 Linear circuit has a straight-line response. As input varies, output varies by factor of 10 larger, producing straight-line output.

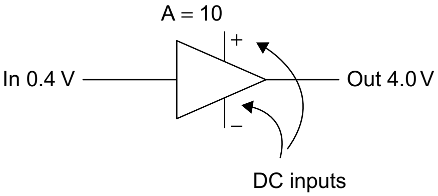

FIGURE 4.2 Block symbol for amplifier. Gain, A, is often given. DC power inputs are not usually shown.

and it is this DC that is ultimately converted into the new, larger output signal. In most cases the DC inputs are not shown in a block diagram. The amplifier processes the input to create an output of the same shape but at a larger amplitude.

The primary characteristic of any amplifier is its *gain*. The gain (usually represented by A) is simply a number equal to the ratio of the output to the input.

$$A = \frac{\text{Output}}{\text{Input}}$$

If the output is 4 volts and the input is 0.4 volt, the gain is simply:

$$A = \frac{4}{0.4} = 10$$

The amplifier multiplies the input by 10 to get the output.

$$\text{Output} = 10 \times \text{Input}$$

Classifying Amplifiers

The amplifier is the most common linear circuit. There are so many different types of amplifiers that we divide them up into different types to distinguish one from another. And there are multiple ways of doing this. Here are the most common.

Small Signal versus Large Signal

Small signal amplifiers are those that, as the name implies, only amplify small signals which are those roughly below about 1 volt. Small signal amplifiers amplify millivolt, microvolt, or nanovolt signals. Large signal amplifiers amplify larger signals and typically amplify the power of a signal rather than the voltage. These are called power amplifiers (PAs).

Frequency Classification

Amplifiers are also categorized by the frequency of the signals they amplify. Some examples are DC amplifiers, audio frequency (AF) amplifiers, intermediate frequency (IF) amplifiers, video amplifiers, radio frequency (RF) amplifiers, and microwave amplifiers.

Configuration Classification

The two main configurations are single-ended and differential. A single-ended amplifier is one in which the input and output are referenced to a common ground. These amplifiers have two inputs, one is the signal and the other is ground. See Figure 4.3A. Normally only the input is shown as the ground is just assumed to be there.

A differential amplifier has two inputs as Figure 4.3B shows. These are usually called the inverting (−) and the non-inverting (+) inputs. Both inputs are referenced to ground. The amplifier is called a differential amplifier because it actually takes the mathematical difference between the two inputs and amplifies the result. One input is subtracted from another, then the difference is amplified by the gain A. The formula for this operation is:

$$\text{Output} = (\text{Input } 2 - \text{Input } 1) \times A$$

Differential amplifiers have one neat feature in that any signal common to both inputs like noise is automatically canceled out. This feature is widely taken advantage of in very small signal amplifiers used in memory chips and high gain amplifiers that amplify small signals from sensors. Noise that is picked up simultaneously on both inputs simply subtracts itself out without bothering the desired small difference signal.

Classification by Class of Operation

One way to categorize amplifiers is to designate the conduction of the transistors in the amplifiers. The primary classes are A, B, AB, C, D, E, and F. There are a few others but these are the most common. Class A amplifiers conduct continuously. We say that the amplification occurs over the full 360 degrees of a sine wave cycle. See Figure 4.4. Note: The small t on the waveforms means time as the voltage is varying over time.

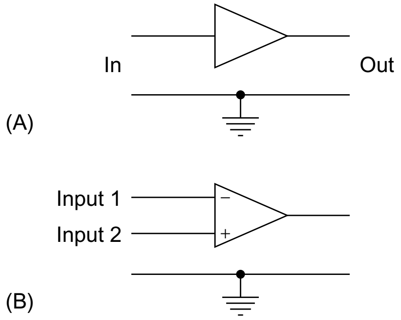

FIGURE 4.3 Single-ended (**A**) and differential input (**B**) amplifiers. Inputs and outputs are referenced to ground.

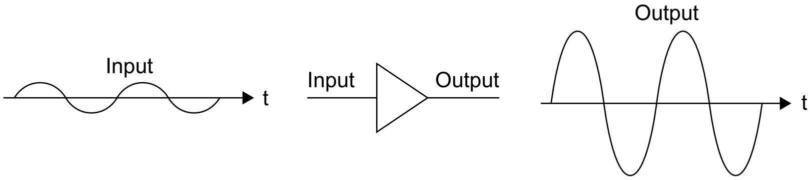

FIGURE 4.4 Class A amplifier conducts continuously.

Class B amplifier transistors only conduct for half a cycle or 180 degrees of a sine wave. See Figure 4.5. Such an amplifier seems useless since it distorts the signal. But if you combine two transistors, one to amplify positive cycles and the other to amplify negative cycles, then combine the two, the complete wave is amplified. Such an amplifier is called a push pull amplifier. The benefit of this arrangement is that the circuit is more efficient.

Class AB amplifiers are a variation of the class B. Class B amps do add a little distortion to the signal around the point where the sine wave crosses zero. This is caused by the transistors not turning on and off precisely at the zero point. This glitch shown in Figure 4.5 is called crossover distortion. To get rid of that, class AB amplifiers allow some small current to flow continuously. The result is less distortion but a little less efficiency.

Class C amplifiers are for RF signals and are usually power amplifiers. They only allow the transistor to conduct for less than 180 degrees of a sine wave input, usually 90 to 150 degrees. It produces massive distortion. However, the amplifier output is made up of an inductor and capacitor (LC) tuned circuit that oscillates at the operating frequency and removes the distortion. These amplifiers are very efficient.

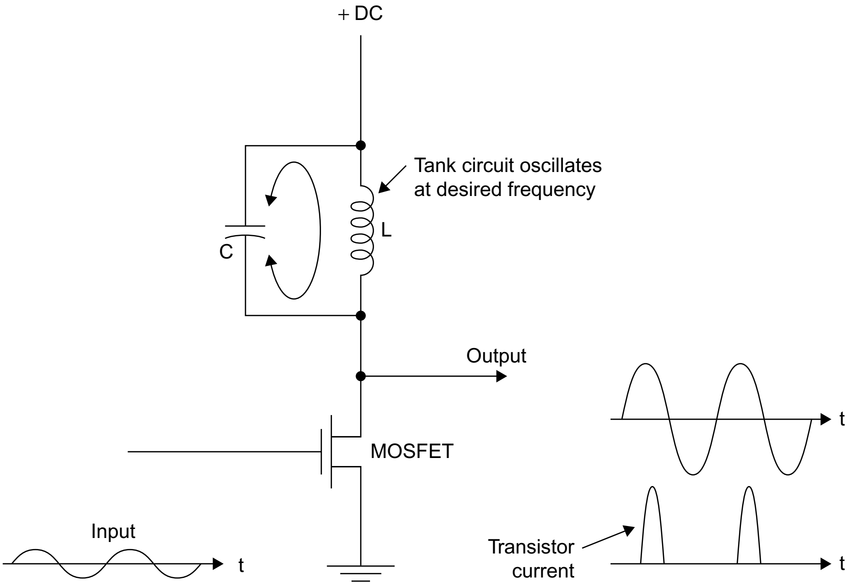

FIGURE 4.6 Class C amplifier only conducts for part of a half cycle, but the current pulse stimulates resonant tank circuit that oscillates at desired frequency.

In a class C amplifier the MOSFET acts like a switch that is turned off and on by the input signal, usually a sine wave. See Figure 4.6. When the MOSFET is on the capacitor charges up to the DC supply voltage and current flows in the inductor creating a surrounding magnetic field. When the transistor turns off, the inductor and capacitor begin to exchange energy and set up an oscillation at the resonant frequency of the LC circuit. This is called a tank circuit. The result is that the energy stored in the tank circuit produces the amplified sine wave output.

Another way of looking at this is that the transistor switch distorts the input creating a pulse waveform that contains lots of harmonics. The tank circuit acts like a selective band-pass filter that lets the fundamental sine wave pass while the harmonics are filtered out.

Don't forget the Fourier theory and harmonics. Remember that a harmonic is an integer multiple of a fundamental sine wave. If the fundamental sine wave is 20MHz, the 2nd harmonic is 40MHz, the 3rd harmonic is 60MHz, the 4th harmonic is 80MHz, and so on. Any non-sine wave signal, like a half sine wave, square wave, or pulse is said to be made up of the fundamental sine wave added to multiple harmonics. A distorted sine wave has the fundamental sine wave in it but also harmonics. This concept is called the Fourier theory after the French mathematician.

Class D amplifiers are a special class called a switching amplifier. It is made up of transistor switches rather than a real linear amplifier. This amplifier chops the input analog signal into high-frequency pulses with a varying width. See Figure 4.7. This process is called pulse width modulation (PWM).

FIGURE 4.7 Class D amplifier uses PWM at higher frequency to switch higher voltages for greater output. Class D amplifiers are more efficient than any other type, and thus do not produce as much heat.

The sine wave audio signal to be amplified is sent to one input of a special amplifier called a comparator along with a higher-frequency triangle wave. The comparator output switches when the triangle wave and sine wave values are equal. The resulting PWM signal is then fed to MOSFET switches to make the signal bigger. The higher amplitude output it then filtered back into an analog signal by a low-pass filter made up of a capacitor and inductor. Most class D amplifiers are audio power amplifiers whose load is a speaker or headphone. For low power less than a few watts, all the circuitry is in a single IC. For higher power, the MOSFETs are larger external devices.

The big benefit of switching amplifiers is that for a given output power they are very efficient. Whereas a class AB amplifier may only be 20 to 30% efficient, the class D is over 90% efficient. This means that the amplifier can be smaller and use less power and dissipates less heat. Class D amplifiers are great for portable battery-operated devices like MP3 players and cell phones.

Classes E and F are special switching amplifier variations used at RF frequencies only. Like the class C amplifier, they use LC circuits to filter out the harmonics they produce. They are very efficient.

Operational Amplifiers

There are many special types of amplifiers. The most widely used is the operational amplifier or op amp. This is a versatile high-gain DC differential amplifier that can be configured with external resistors, capacitors, diodes, etc. to perform a wide variety of amplification functions. The op amp may be the most widely used type of amplifier because of its versatility.

Figure 4.8 shows the most common op amp configurations. In most cases, the resistors are external to the IC amplifier. Note that the gain is determined by the values of the external resistors. Note formulas for gain (A).

A variation of the op amp is the instrumentation amp. See Figure 4.9. It is a combination of multiple op amps that make it very useful in industrial applications such as amplifying small signals from sensors. Again the gain is determined by the resistor values. You can make this amplifier from individual op amps but usually you just buy it as a single integrated circuit. The external resistor sets the gain.

A variable or programmable gain amplifier is one whose gain can be controlled from an external DC input.

Amplifier Specifications

While you really do not need to know much about what the circuitry in an amplifier IC is, you do need to understand the specifications. Here are the most common specifications to look for.

As mentioned before, gain is the primary amplifier characteristic. It is usually a voltage or power ratio, depending on the type of amplifier.

$$\text{Voltage gain is output voltage over input voltage: } Av = \frac{Vo}{Vi}$$

$$\text{Power gain is output power over input power: } Ap = \frac{Po}{Pi}$$

Many amplifiers have their gain expressed in decibels (dB). A dB is a gain measurement based on a logarithmic scale rather than a linear scale. This has the advantage of being able to express large and small gains in smaller numbers.

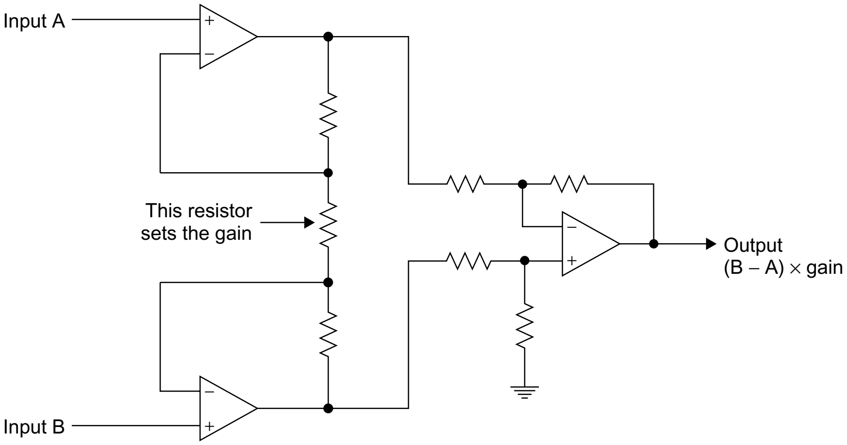

FIGURE 4.9 Instrumentation amplifier widely used to amplify small sensor signals in industrial applications.

And gains of multiple stages can be added rather than multiplied. To calculate dB gains you used these formulas:

$$\text{Voltage gain: dB} = 20 \log (Av)$$

$$\text{Power gain: dB} = 10 \log (Ap)$$

In these formulas, log means the common (base 10) logarithm of the voltage or power gain. The logarithm (log) is easy to find using a scientific calculator.

For example, a voltage gain of 50 expressed in dB is:

$$\text{dB} = 20 \log 50 = 20\,(1.7) = 34\ \text{dB}$$

A power gain 300 expressed in dB is:

$$\text{dB} = 10 \log 300 = 10(2.5) = 25\ \text{dB}$$

Input Impedance

Input impedance is the load seen by the signal source to the amplifier. It is usually resistive but typically also has some capacitance across it. Figure 4.10A shows an equivalent circuit of an amplifier. Note the input resistance. That is the input impedance. It may be as high as several megohms or could be as low

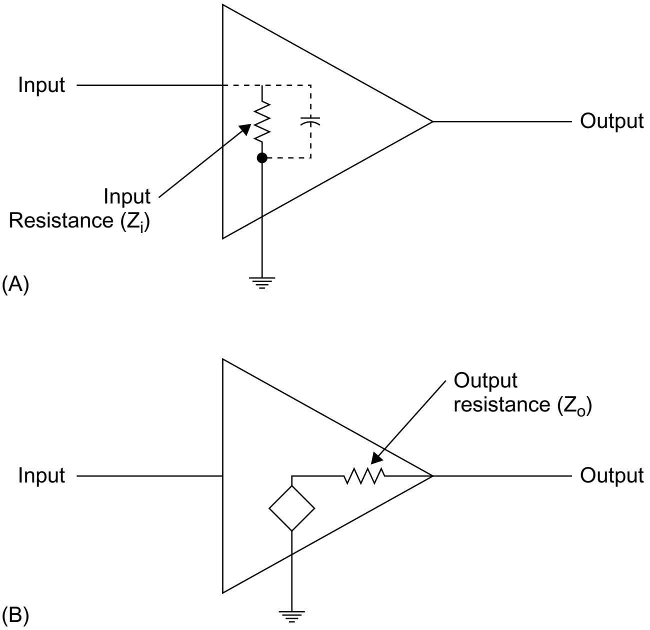

FIGURE 4.10 Amplifier input impedance **(A)** and output impedance **(B)**.

as, say, 50 ohms. Usually the higher the better for voltage amplifiers but not for power amplifiers.

Impedance

The term *impedance* means opposition to current flow. It is actually the combined opposition offered by resistance plus any capacitive or inductive reactance. If there is no reactance, the impedance is just the resistance so the two terms can be used interchangeably. Impedance is represented by the letter Z.

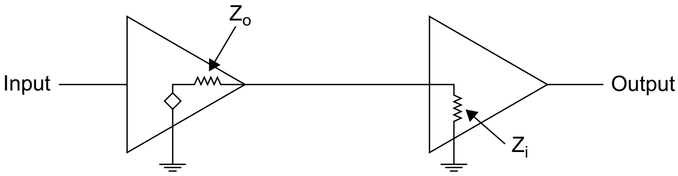
Output Impedance

Amplifiers act as signal generating sources because they essentially just create a new higher voltage or higher power signal with the same shape as the input. They appear as a signal generator to the next circuit or load. Figure 4.10B shows the amplifier as a generator shaped as a diamond. It has an internal impedance or series resistance called the output impedance. It is not a real resistor but it is there and it appears in series with whatever load is connected which may be another amplifier or something else.

Figure 4.11 shows the amplifier connected to another amplifier. Note that the output impedance for amplifier A_2 and the load form a voltage divider so some of the amplification is lost to the voltage divider effect. The input impedance of A_2 is the load for the output impedance of A_1.

Cascading Amplifiers

If an amplifier does not have enough gain, then multiple amplifiers can be cascaded one after the other to give the needed gain. One amplifier amplifies the output of the next and so on. See Figure 4.12. To calculate the overall gain of an amplifier you just multiply the gains as shown in the figure. This procedure assumes that one amplifier does not load the next. That is, the output impedance of each amplifier is assumed to be zero and the input impedance of the next amplifier is assumed to be infinite. That way, there is no voltage divider effect that lowers the gain.



Z_o and Z_i form a voltage divider that lowers or cancels gain

FIGURE 4.11 When one amplifier feeds another, input and output impedances form a voltage divider that attenuates the signal and offsets some of the gain.

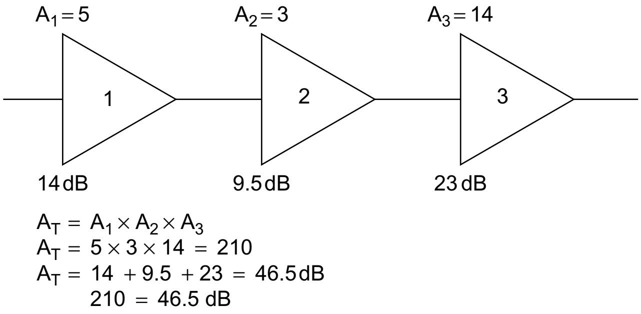


FIGURE 4.12 Cascading amplifier provides more gain. Total gain is product of individual gains or sum of dB gains.

If the amplifier gains are given in dB, you just add the dB figures to get the total gain.

Efficiency

Efficiency is the ratio of the output power to the input power expressed as a percentage.

$$\%\ \text{Eff} = \frac{\text{Po}}{\text{Pi}} \times 100$$

An amplifier takes the DC supply voltage and converts it into the AC output. The efficiency expresses how well the amplifier does this. Any lost power usually gets converted to heat which is not good. Nevertheless, some heat will always be generated just because electronic circuits are not perfect. High efficiency is a good thing of course, but often efficiency is traded off for better linearity, fidelity, and lower distortion of the signal.

Class A amplifiers have the poorest efficiency commonly in the 10 to 30% range. Classes B and AB are more efficient in the range of 50 to 70%. Class C amps have an efficiency of 70 to 85%. Class D amplifiers are the best with efficiencies in the 80 to 95% range.

Frequency Response

This is a measure of the range of frequencies that amplifiers cover. DC amplifiers may only cover DC up to about a few hundred Hz. Audio amplifiers may cover voice frequencies from 300 to 3000 Hz or stereo amps that cover 20 Hz to 20 kHz. IF amplifiers may only cover a specific band, say, 455 kHz, 9 MHz, 45 MHz, 70 MHz, or some other popular IF value. Op amps amplify signals from DC up to some very high frequency as high as several hundred MHz in some cases.

RF amplifiers cover high radio frequencies from a few MHz up to microwaves from 1 to 100 GHz. Their frequency and range of coverage is usually set by a filter or LC tuned circuit.

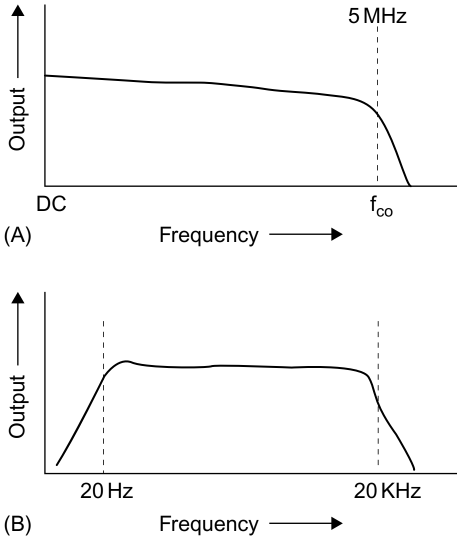

FIGURE 4.13 Frequency-response curves show output versus input frequency. Curve in **(A)** is response of op amp that extends from DC to 5-MHz cut-off frequency. Curve in **(B)** is response of common stereo audio amplifier.

Figure 4.13A shows the response curve for an op amp with an output down to DC and up to the cut-off frequency (f_{co}) or 5 MHz. Figure 4.13B is the response curve of a stereo amplifier with a range of 20 Hz to 20 kHz.

Output Capability

This specification indicates the range of output signals the amplifier is capable of. It is usually stated as a maximum voltage swing or as a maximum amount of output power. In both cases, the maximum output is usually given for a given value of load resistance. For example, an op amp may be capable of producing an output of ±12 volts across a 2 K load. A power amplifier may produce a maximum output of 10 watts across an 8 ohm speaker load or, say, 50 watts across a 50 ohm antenna load.

Filters

A filter is a frequency sensitive circuit that is designed to pass some frequencies, but reject others. There are various ways of making filter circuits that will accept some frequencies, but greatly attenuate others. There are literally thousands of applications for such circuits. But the main use of filters is to retain a desired signal, but eliminate interference and noise.

There are four basic types of filters: low-pass (LPF), high-pass (HPF), bandpass (BPF), and band-reject (BRF). The names, of course, tell their function.

A low-pass filter (LPF) is a circuit that passes all frequencies between DC and some upper cut-off frequency (f_{co}). All frequencies above the cut-off frequency are rejected. Figure 4.14A shows the response curve of an LPF. This is a plot of the filter output amplitude versus frequency. Note the gradual slope

as signals above the cut-off frequency (f_c) are reduced in amplitude. The block symbol is how LPF is represented in some diagrams.

A high-pass filter passes frequencies above the cut-off and greatly attenuates those below the cut-off. Figure 4.14B shows the ideal response curve of an HPF. Note the HPF symbol.

Band-pass filters (BPF) pass a certain range of frequencies, but reject all those above and below that range. Figure 4.14C shows the practical response curve of a BPF. Note that there are two cut-off frequencies, one above and one below the center frequency f_c. The difference between the upper and lower cut-offs is called the filter bandwidth (BW):

$$BW = f_2 - f_1$$

This is the range of frequencies passed. Again note the schematic symbol for a BPF.

Figure 4.14D illustrates the curve for a band-reject or notch filter. It is used to eliminate one single frequency and those close around it.

Note in the block symbols in Figure 4.14 that each has three waves representing high, middle, and low frequencies. The wave with the slash through it means that these frequencies are cut out or greatly attenuated.

Filters can be implemented in many ways. Resistor and capacitor (RC) filters are common as are inductor and capacitor (LC) filters. You can make filters with op amps called active filters. Other filters are made with mechanical vibrating elements, a ceramic or quartz crystal, or a special surface acoustic wave (SAW) filter. Many filters today are made with digital signal processing (DSP). These will be discussed in Chapter 6.

Oscillators

An oscillator is a circuit that generates a signal. It is usually a sine wave or a rectangular wave. The electronic symbols used to represent an oscillator are given in Figure 4.15.

The main specification of an oscillator is its output frequency. Most oscillators have a fixed frequency but there are oscillators whose frequency can be varied. A tunable frequency oscillator is called a variable frequency oscillator (VFO). You can often tune it by turning a knob that varies a capacitor or inductor to change the frequency. Some oscillators are tuned by an external voltage. These are called voltage-controlled oscillators (VCOs). By varying the value of a DC input voltage, the frequency is changed.

The frequency of an oscillator is set by some frequency determining element or circuit. That circuit may be made up of resistors and capacitors (RC), inductors and capacitors (LC), or a crystal. A crystal is a thin piece of quartz that can be made to vibrate at a very precise frequency. It maintains its frequency very closely unlike RC or LC networks that can drift with temperature or change from vibration or other conditions. Crystals come in a small metal package and are used to set the frequency in most oscillators today.

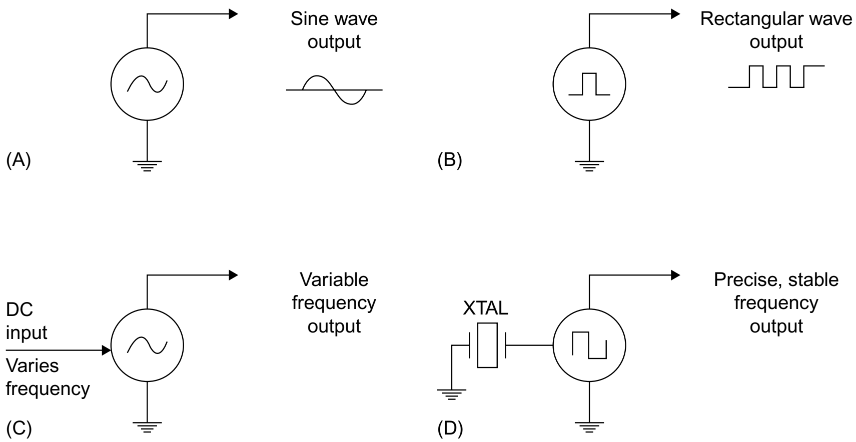

FIGURE 4.15 Types of oscillators and their symbols. **(A)** Sine wave. **(B)** Rectangular pulse. **(C)** VCO. **(D)** Crystal clock oscillator.

A special type of oscillator is called a clock oscillator. It is used as an accurate time and frequency source. The frequency determining element is usually a quartz crystal that vibrates at a precise frequency and is very stable. The clock signal is used to operate all the circuits in synchronism. An example is the clock oscillator in a PC that sets the speed of calculations. Sometimes you will see a quartz crystal (XTAL) symbol drawn with the oscillator symbol to illustrate this. See Figure 4.14D.

Mixers

A mixer is a circuit that takes two input signals and mixes them in a special way to produce new output signals. There are two types of mixers, linear and non-linear.

A linear mixer is one that takes the input signals and just adds them together. You can do this with some resistors as shown in Figure 4.16A. The sum of both input signals appears across the output resistor.

You can also make a linear mixer with an op amp as shown in Figure 4.16B. This op amp circuit is called a summer. Setting the resistor values allows you to mix and add gain at the same time. A good example of a linear mixer is those used by musicians so they can mix the outputs from microphones and musical instruments so they can all be amplified as one by the power amplifiers that drive the speakers. Note the variable resistors called pots that are used as amplitude or volume controls.

A non-linear mixer takes two input signals and effectively multiplies them together. The result is that the mixer produces four output signals. Figure 4.17 shows the symbol for a mixer. The inputs are frequencies 1 and 2 or f_1 and f_2.

The mixer outputs are f_1, f_2, and ($f_1 + f_2$) or the sum, and ($f_1 - f_2$) the difference. The sum and difference frequencies are the ones of most interest. Usually a filter is used at the output of the mixer to select the desired frequency and eliminate the others. If the lower difference frequency is selected, the mixer is often called a down converter. If the sum frequency is selected, the mixer is called an up converter. The mixer is a way to translate a frequency to another higher or lower frequency that is better for processing. Any signal amplitude or frequency variations on the inputs are accurately carried through to the new output frequency.

Phase Detector

A phase detector is a mixer-like circuit that puts out a signal that is proportional to the phase difference between two input signals of the same frequency. See Figure 4.18. A phase shift is a time difference between two signals of the

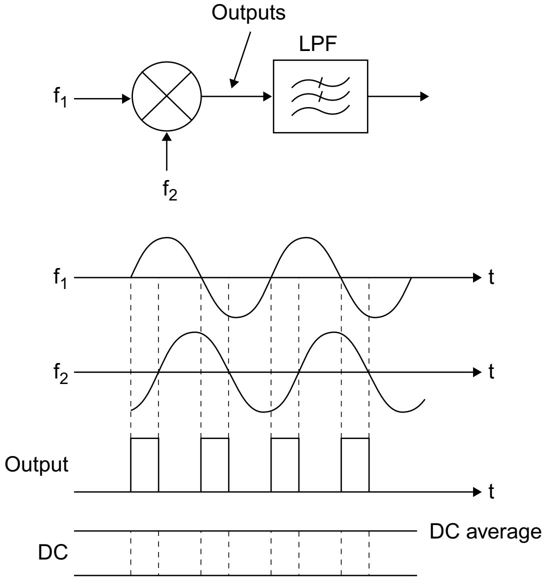

FIGURE 4.18 Phase detector converts phase shift into proportional DC average.

same frequency. We sometimes need to know how much phase shift is present. The phase detector produces a series of output pulses whose width is proportional to the phase difference. Passing the pulses through a low-pass filter smoothes them into a proportional DC voltage.

Filtering Pulses into DC

A common occurrence in electronic circuits is the filtering of pulses into a DC voltage. You saw this back in Figure 3.15 where positive pulses from a sine wave rectifier are smoothed into a DC voltage. It is the capacitor that charges up and stores the pulse voltage. Then between pulses the capacitor discharges into the load maintaining a near constant DC voltage. The low-pass filter usually includes a capacitor so performs the same function in the phase detector of Figure 4.18. The output is a proportional average DC output.

Phase-Locked Loops

The phase-locked loop (PLL) is a frequency- and phase-sensitive feedback control circuit. It consists of three major parts: a mixer or phase detector, a low-pass filter (LPF), and a voltage-controlled oscillator (VCO), as shown in Figure 4.19. The signal from the VCO is compared to the input signal. If there is a frequency (or phase) difference between the two, an error signal is generated. This error signal is filtered by the LPF into a varying DC level and is used to control the VCO frequency. This is the feedback signal.

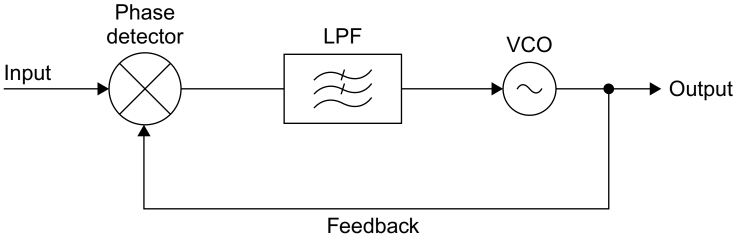

FIGURE 4.19 Phase-locked loop.

If the VCO frequency, f_o, differs from the input reference signal frequency, f_o the f_r the phase detector sees this as a phase shift. This causes the phase detector to produce an error signal. This error signal is filtered into a varying DC signal that is used to control the VCO.

The VCO can be either a sine wave oscillator or a rectangular wave oscillator depending upon the desired waveshape of the output. In either case, the VCO output frequency is made directly proportional to the DC control voltage. There is a linear voltage-to-frequency relationship in the VCO. This means that changing the control voltage produces a proportional change in output frequency. If the voltage goes up, so does the frequency.

Now if an input reference signal whose frequency is near that of the VCO is applied to the PLL, the phase detector will produce an output voltage proportional to the frequency difference. This signal is filtered and the resulting DC control voltage is applied to the VCO. The control voltage is such that it forces the VCO frequency to move in a direction that reduces the error signal. This means that the VCO frequency will change until it is equal to the input reference signal frequency. When this happens, the two signals are synchronized or “locked.” The phase difference causes the phase detector to produce the DC voltage at the VCO input to keep the PLL locked to the input signal.

If the input reference signal changes, then the phase detector will recognize a frequency (or phase) difference between the input and the VCO output. As a result, the LPF will produce a different DC control signal that will force the VCO to change such that it is equal to the new input frequency. As you can see then, the PLL will “track” an input signal frequency as it changes.

The range of frequencies over which the PLL will track an input signal and remain locked is known as the lock range. This is a range of frequencies above and below the VCO free running frequency. The PLL can track and “lock” to any input frequency in this range. If an input signal out of the lock range is applied, the PLL will not synchronize.

If the input signal is initially outside of the lock range, the PLL will not lock. But, the PLL will jump into a locked condition as soon as the input frequency gets close to the VCO frequency. In other words, the PLL will “capture” the incoming signal if it is close enough to the VCO frequency. Once the input signal is captured, the PLL is locked and will track further changes in the input signal frequency.

The range of frequencies over which a PLL can capture a signal is known as the capture range. Like the lock range, it too is centered on the free running frequency. But the capture range is narrower than the lock range. The PLL acts as a frequency sensitive circuit over a narrow range of frequencies.

Since the PLL will only capture and lock on to input signals within a certain narrow band, the PLL acts like a band-pass filter. For that reason, the PLL is an excellent signal conditioner. You can take a noisy input signal or one with undesirable interference on it and filter it with a PLL. The PLL will lock on to only the desired frequency component of the input. The VCO reproduces the input signal at the same frequency but with the noise and interference removed. The PLL not only cleans up a signal but also can track it if its frequency changes.

The PLL is widely used for a variety of purposes. It is used to recover the clock signal in some wireless applications. It is used to recover the original signal in frequency modulation (FM) radio. It is used to multiply a frequency by a fixed factor. It can be used for motor speed control. Almost all electronic products of some kind contain a PLL.

Frequency Synthesizers

One of the most popular uses of the PLL is in frequency synthesizers. A frequency synthesizer is a very stable signal source that can be varied over a specific range of frequencies in finite increments or steps. Frequency synthesizers are used as precision signal generators for test and measurement purposes and replace more conventional oscillator circuits as the primary signal sources in radio transmitters or receivers.

The big advantage of a PLL synthesizer is its ability to generate a wide range of frequencies with great accuracy and stability by using only a single stable signal source. For example, a PLL synthesizer with a single crystal controlled reference input can readily generate hundreds or even thousands of discrete frequencies that are as stable as the crystal reference. By using a synthesizer as the initial signal source in a transmitter, a wide range of channels can be obtained with a single crystal. When many channels must be used, a synthesizer greatly reduces the cost since crystals are expensive.

The synthesizer circuit in Figure 4.20 shows that it is a PLL with a frequency divider connected between the VCO output and the phase detector. The frequency divider is a circuit that divides its input frequency by some whole number. For example, the output of a divider with a division factor of 12 and an input of 48 MHz is 48/12 = 4 MHz.

The frequency synthesizer PLL also uses a stable, crystal oscillator input to the phase detector. This is usually derived from a crystal oscillator. When the PLL is locked, the stability and accuracy of the VCO output will be the same

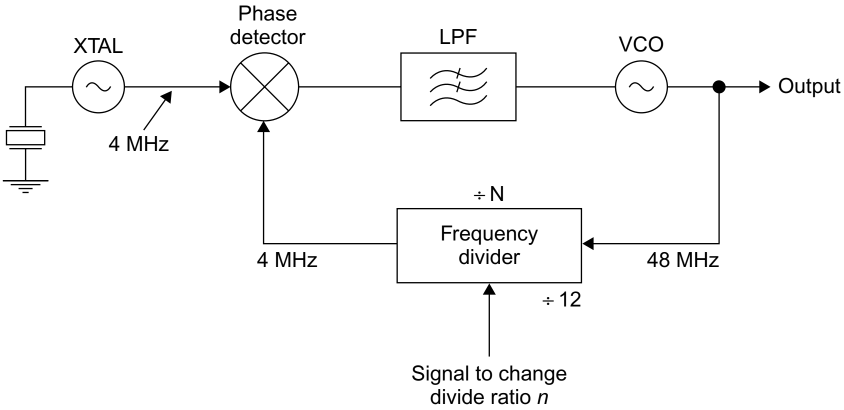

FIGURE 4.20 Frequency synthesizer using phase-locked loop. Changing the divider ratio changes the frequency.

as that of the reference input. The frequency divider is usually made so that its divide ratio can be changed by setting a switch or changing the control inputs. Changing the division ratio changes the output frequency at which the loop will lock.

The reason for this is that the two inputs to the phase detector must always be equal in frequency if a locked condition is to be achieved. The reference frequency is fixed so the only thing that can change is the VCO output if the divider ratio is altered. If the loop is locked, the output of the divider will be 24 MHz no matter what the divide ratio is. Therefore, with an output of 4 MHz, a divide by 6 circuit must have a 24 MHz input. Since the VCO output is the divider input, the VCO and synthesizer output will be 24 MHz too.

As you can see, changing the divide ratio changes the output frequency. In this circuit, if the divide ratio is changed in integer values between 6 and 12, the output frequencies will be as shown in Table 4.1. With this setup, the output is switched in 4-MHz increments.

If the input reference is made 1 MHz, then when the divide ratio is changed, the output frequency will step in 1-MHz increments. By carefully selecting the reference frequency and the divide ratio, it is possible to synthesize practically any range of frequencies in many increments from subaudio to microwave.

Note one final fact about the PLL circuit in Figure 4.20. If the reference is considered the input, and the VCO is considered the output, then the PLL is acting as a frequency multiplier. Here the output is 12 times the input. You will occasionally see the PLL used as a frequency multiplier in some applications.

The PLL synthesizer is a very versatile circuit. It is commonly available in integrated circuit form. PLL frequency synthesizers are used in TV channel selectors, stereo receivers, CB radios, cellular telephones, and other two-way radios. In such equipment the divider ratio is supplied by an input keyboard or

a built-in microcomputer programmed to supply the desired divide factor for a selected output frequency.

Power Supplies

A power supply is, as its name implies, a source of power to an electronic circuit. Most electronic circuits operate from DC as they process AC or DC signals. The most common power supply is the one that gets its input from the standard AC wall outlet that supplies 120 volts at 60 Hz. This common voltage is then converted by the power supply into one or more DC voltages that go to operate the TV set, computer, or other equipment. This section discusses the main components and circuits of a power supply.

Batteries

One of the most widely used power supplies is a battery. A battery is a great source of DC by itself and no AC source is needed. Batteries were the very first form of voltage sources for electrical circuits and they are still widely used today. What would we do without the batteries for our cell phones, iPods, cordless telephones, laptop computers, and remote controls? Just remember that a special form of power supply is the battery charger that normally uses AC to recharge lead-acid, nickel cadmium, nickel metal hydride, and lithium-ion batteries.

Standard Power Supply

A very common AC to DC power supply is shown in Figure 4.21. It normally consists of a transformer that translates the 120 volt AC line voltage into a higher or lower voltage as needed by its step up or step down characteristics. Today, since most equipment uses ICs, a lower AC voltage is needed. The lower

AC voltage is then converted into a pulsating DC voltage by a rectifier. A rectifier is one or more diodes that act like polarity sensitive switches to change the positive and/or negative sine half cycles into pulses of DC. A filter is then used to smooth the pulses into a more constant DC voltage. The filter is usually a large capacitor that charges up to the peak of the DC pulses then only discharges very slowly into the load.

Regulators

A regulator is a circuit that maintains a fixed DC output voltage of a desired value. The DC produced by the power supply at the filter output will vary over a wide range as the AC input line voltage changes. Any changes in the load meaning variations in current taken from the supply will also cause the output voltage to vary. A regulator absorbs those variations and creates a constant DC output suitable for powering ICs and other electronic circuits. Common DC output voltages are 3.3, 5, 12, 15, and 24 volts. Other typical DC supply voltages are 1.2, 1.8, 6, and 48 volts.

There are two types of regulators, linear and switching. A linear regulator inserts a transistor in series between the power supply output and the load. If the load varies, circuitry in the regulator adjusts the conduction of the transistor so that a constant voltage is maintained. It is as if a resistor in series with the load forms an adjustable voltage divider. If the output voltage drops, the series transistor conducts more to keep the output voltage the same. If the output increases, the transistor conducts less to decrease the voltage and maintain the same value.

The other type of regulator is the switching regulator. It puts a transistor in series with the load as well but the internal circuitry turns the transistor off and on at a high rate of speed. By varying the duty cycle (ratio of on to time for one period) of the on–off pulses the average DC output may be varied. Then if any output voltage changes are sensed, the duty cycle is adjusted to ensure that the average output stays the same.

Duty Cycle and PWM

The duty cycle is the ratio of the pulse width to the period of a rectangular wave as shown in Figure 4.22. The period is the reciprocal of the frequency of the signal or $T = 1/f$. It is constant. The on-time is the duration of the pulse voltage (t). The pulse duration can vary depending upon what the application is. If the period is 50 milliseconds and the pulse on-time is 10 milliseconds, the duty cycle (D.C.) is:

$$\text{D.C.} = 10/50 = 0.2 \times 100 = 20\%$$

Circuits can be made to change the on-time so that the duty cycle can be varied from a few percent to nearly 100%. This is called pulse width modulation (PWM). It was introduced earlier in the class D amplifier discussion. PWM is widely used in switching power supplies like regulators and DC–DC converters.

(*Continued*)

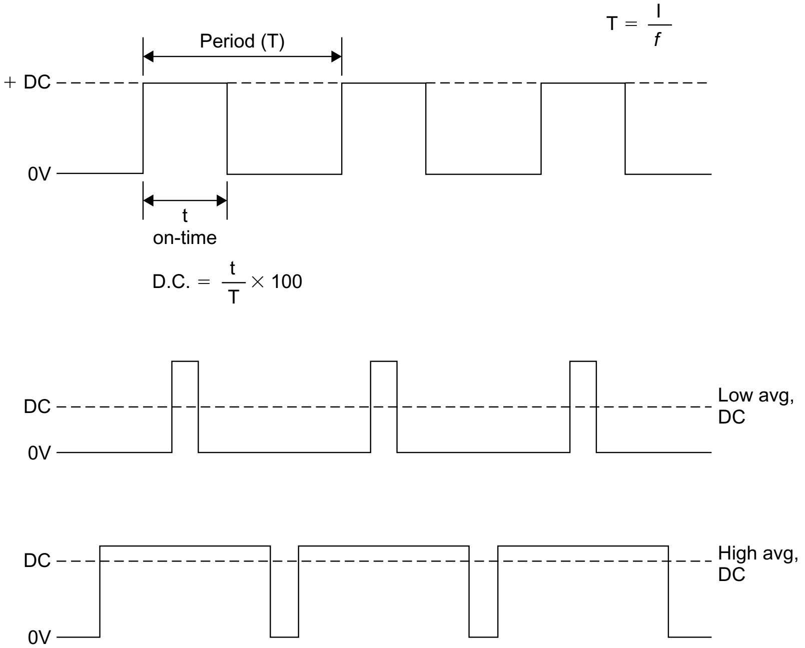

FIGURE 4.22 Concept of duty cycle and how varying pulse widths can be filtered into a proportional DC average voltage. avg, average.

Keep in mind that if you filter the pulses into an average proportional DC with a capacitor or LPF, you can vary the DC from some low value with a low duty cycle or some higher value with a higher duty cycle.

Linear regulators work very well but are not very efficient as they waste power in the series transistor. Typical efficiency is 10 to 40%. A switching regulator is far more efficient as it is off for a large part of the time. Efficiencies in the 70 to 95% range are common.

DC—DC Converters

A DC–DC converter is a circuit that does what its name implies. It translates one DC voltage to another. It can take the voltage from a 12 volt battery and generate several hundred or thousand volts. Or it can take a 4.2 volt battery and produce voltages of 3.3 or 2.5 volts and 15 volts. By building one DC power supply, several other output voltages can be obtained by using different DC–DC converters.

Bus-Oriented Architecture

Many power supplies have what we call a bus architecture. See Figure 4.21. The DC power supply produces one main output voltage. That voltage is applied to a common DC bus. A bus is just the name for the two + and − DC lines that carry the voltage. Then, regulators and DC–DC converters are used to generate the voltages needed by the equipment. Again see Figure 4.21.

Power Management

Many power supplies today include a circuit that manages the power supply voltages. It is usually a single IC that does things like turn on the various DC voltages in a power supply in a specific sequence. Some ICs require multiple DC voltages and they must be turned on one at a time in a specific sequence. In addition, the power management chip does things like monitor current usage. If one power supply is not being used, meaning current not being drawn from it, that part of the power supply is shut down to conserve power. A good example of this is the power management in a laptop computer or cell phone that monitors and controls all DC power to preserve the battery charge for longer life. Some other functions performed by power management chips are voltage monitoring with voltage alarm if a voltage fails, temperature monitoring, fault detection, over voltage or under voltage detection, and power control. Some power management chips also have the battery charging circuits built in. Every cell phone and laptop has one of these.

Inverters

An inverter is a power supply that converts DC into AC. A common unit converts 12 volts from a car battery into standard 120 volt 60Hz AC. With an inverter you can operate common household lights and appliances from a battery.

A special variation of an inverter is the uninterruptible power supply (UPS). These are widely used with computers and networks to provide power even during loss of AC input from the power line. A battery operates an inverter that is used to power the computers and other equipment. If the AC power fails, the equipment continues to operate. The battery is continuously charged by a built-in battery charger that operates from the AC power line.

Solar Power System

Any home or business solar power system is similar to a large UPS (see Figure 4.23). It uses the solar panels to charge a bank of batteries that store the energy for use later when the sun goes down. The inverters convert the DC into standard 120/240 volt AC to power the house. In some cases, unused power is sent back to the power grid.

Project 4.1

Build a Kit

If you are really serious about electronics, then one of the first things you should do is build a kit. A kit, in case you really do not know, is a complete package of electronic parts to make a specific product. You build it yourself by placing components on a printed circuit board (PCB) and soldering them in place. There is no better way to see how electronic products get put together than to handle the wide variety of parts. It is a great learning experience.

There are two main questions to answer about this project. First, what kind of kit do you want? Second, can you learn to solder? You will have to answer the first question, but as for the second, yes, you can learn to solder. It's not that hard.

One way to get an overview of the kits available is to obtain catalogs from the sources mentioned earlier in this book. You can order a print copy online and see the whole range of kits available. Go to:

All Electronics: www.allelectronics.com
Elenco Electronics: www.elenco.com
Jameco: www.jameco.com
Kelvin: www.kelvin.com
Ramsey: www.ramseyelectronics.com

What I recommend is to get a kit related to one of the topics in this chapter. A power supply is a great choice, and it will give you a variable DC voltage source that you can use in future projects. The same is true for a basic audio amplifier. A solar panel kit is a good one also. Most of the companies have lots of radio- and wireless-related kits, but save these for the later chapters on wireless products.

Don't forget to get a small soldering iron (25 watts or so) with a small tip and some solder. You will also need a few hand tools such as a wire stripper, needle-nose pliers, side cutters, and a small screwdriver, if you do not already own these.

Electronic Circuits: Digital

Practically Everything Is Digital These Days

In this Chapter:

- Binary number system.
- Logic gates and flip-flops.
- Common combinational and sequential circuits.
- Semiconductor memory.
- Programmable logic devices.
- Analog-to-digital and digital-to-analog conversion.

INTRODUCTION

Recall that there are two basic types of electronic signals—analog and digital. A digital signal is one that varies in discrete steps. Unlike an analog signal, which varies continuously, a digital signal has two levels or states. The signal switches or changes abruptly from one state to the other.

Figure 5.1 shows a DC digital signal that switches between two known levels such as zero volts or close to it (<0.1 volt) or 0 V and +3.3 V. The positive voltage can be anything between about 1 volt and 12 volts with 3.3 and 5 being the most common.

Digital signals with two discrete levels are also referred to as *binary signals. Binary* means two—two states or two discrete levels of voltage.

Humans use the decimal number system that represents quantities with digits 0 through 9. However, digital equipment and computers do not. Internally, digital equipment processes binary data.

BINARY NUMBERS

The binary number system is a set of rules and procedures for representing and processing numerical quantities in digital equipment. Because the base of the binary number system is 2, only two symbols (0 and 1) are used to represent any quantity. The symbols 0 and 1 are called *binary digits* or *bits*. For example, the 6-bit number 101101 represents the decimal number 45. Your understanding of how digital circuits, microprocessors, and related equipment process data is tied directly to an understanding of the binary number system.

The reason for using binary numbers in digital equipment is the ease with which they can be implemented. The electronic components and circuits used to represent and process binary data must be capable of assuming two discrete states to represent 0 and 1. Examples of two-state components are switches and transistors. When a switch is closed or on, it can represent a binary 1. When the switch is open or off, it can represent a binary 0. A conducting transistor may represent a 1, whereas a cut-off transistor may represent a 0. The representation may also be voltage levels. For example, a binary 1 may be represented by +3.3 V and a binary 0 by 0 V as previously shown in Figure 5.1.

Binary-to-Decimal Conversions

The binary system is similar to the decimal system in that the position of a digit in a number determines its weight. Recall that in the decimal system the weights are powers of 10. The right-most digit is units or 1's, and then 10's, 100's, 1000's, and so on, moving from right to left from one digit to the next. The position weights of a binary number are powers of 2:

$2^0 = 1$
$2^1 = 2$
$2^2 = 4$
$2^3 = 8$
$2^4 = 16$
$2^5 = 32$
$2^6 = 64$
$2^7 = 128$
$2^8 = 256$

The position weights of an 8-bit binary number follow:

Bit position	2^7	2^6	2^5	2^4	2^3	2^2	2^1	2^0
Weight	128 (MSB)	64	32	16	8	4	2	1 (LSB)

The most significant digit or bit (MSB) and the least significant bit (LSB) are identified.

Now let's evaluate the decimal quantity associated with a given binary number, 101101. You simply multiply each bit by its position weight and add the values to get the decimal equivalent, 45.

Position weight	32	16	8	4	2	1
Binary number	1	0	1	1	0	1

$1 \times 1 = 1$
$0 \times 2 = 0$
$1 \times 4 = 4$
$1 \times 8 = 8$
$0 \times 16 = 0$
$1 \times 32 = 32$
Decimal equivalent 45

You can see that positions with a 0 bit have no effect on the value. Therefore, they can be ignored. To quickly determine the decimal equivalent of a binary number, simply sum the weights of the positions containing a 1 bit. For example, in the number 11101, the weights of those positions with a 1 bit from right to left are 1 + 4 + 8 + 16 = 29.

Using Hardware to Represent Binary Quantities

Switches are widely used to enter binary data into computers and digital equipment. If the switch is set to the up position, a binary 1 is represented. If the switch is down, a binary 0 is represented. The switch contacts can be open or closed depending on the circuit in which the switch is connected. Figure 5.2 shows a group of slide switches set to represent a binary number, 11000101 or 197.

Indicator lights such as light-emitting diodes (LEDs) are sometimes used to read out binary data in digital equipment. An "on" light is a binary 1 and an "off" light is a binary 0. See Figure 5.3. The decimal value being represented by the display is 178.

Decimal-to-Binary Conversions

You may find it necessary to convert decimal numbers into their binary equivalents. This can be done by dividing the decimal number by 2, dividing the quotient by 2, dividing that quotient by 2, and so on, recording the remainders until the quotient is zero. The remainders form the binary equivalent.

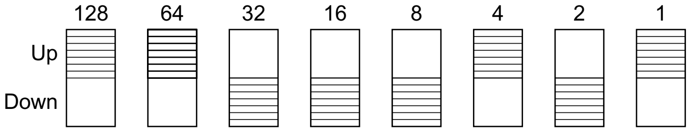

FIGURE 5.2 Off/on switches are used to enter binary data into digital circuits.

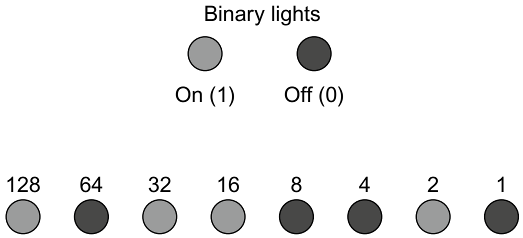

FIGURE 5.3 How lights or LEDs are used to represent binary data.

In the following example, we convert the decimal number 57 to its binary equivalent.

Quotient	Remainder
$57 \div 2 = 28$	1 (LSB)
$28 \div 2 = 14$	0
$14 \div 2 = 7$	0
$7 \div 2 = 3$	1
$3 \div 2 = 1$	1
$1 \div 2 = 0$	1 (MSB)

You can always check your work by reconverting the binary number back to decimal using the procedure described earlier. Also, keep in mind that some scientific calculators can do binary-to-decimal and decimal-to-binary conversions.

Another name for a binary number is *binary word*. The term *word* is more general. It refers to a fixed group of bits that can mean numbers, letters, or special characters and codes. We say that digital equipment processes *binary data words*.

All digital circuits and microcomputers work with a fixed-length binary word. A common binary word length in microcomputers and other digital equipment is 8 bits. All data storage, processing, manipulation, and transmission are carried out in 8-bit groups. Word lengths of 4, 8, 12, 16, 32, and 64 bits are common in digital equipment.

An 8-bit word is usually called a *byte*. In data communication applications, an 8-bit word is sometimes called an *octet*. A 4-bit word is sometimes referred to as a *nibble*.

Maximum Decimal Value for N Bits

The number of bits in a binary word determines the maximum decimal value that can be represented by that word. This maximum value is determined with the formula:

$$M = 2^N - 1$$

where M is the maximum decimal value and N is the number of bits in the word.

For example, what is the largest decimal number that can be represented by 4 bits?

$$M = 2^N - 1 = 16 - 1 = 15$$

With 4 bits, the maximum possible number is binary 1111, or decimal 15.

The maximum decimal number that can be represented with 1 byte is 255 or 11111111. An 8-bit word greatly restricts the range of numbers that can be accommodated. But this is usually overcome by using larger words.

There is one important point to know before you leave this subject. The formula $M = 2^N - 1$ determines the maximum decimal quantity (M) that can be represented with a binary word of N bits. This value is 1 less than the maximum number of values that can be represented. The maximum number of values that can be represented (Q) is determined with the formula:

$$Q = 2^N$$

With 8 bits, the maximum number of values is 256 or 0 through 255.

Table 5.1 gives the number of bits in a binary number and the maximum number of states that can be represented.

BCD and ASCII

The binary numbers we have been discussing are usually referred to as pure binary codes. But there are other types of binary codes. For example, the binary-coded decimal (BCD) system is popular. BCD is a hybrid code between the binary and decimal systems. It was developed in an attempt to simplify the conversion processes between the two systems and to improve human–machine communication.

TABLE 5.1 Number of Bits in Binary Number and Maximum Number of States

Number of Bits	Maximum States
8	256
12	4096 (4 K)
16	65,536 (64 K)
20	1,048,576 (1 M)
24	16,777,216 (16 M)
32	4,294,967,296 (4 G)

Note: K = kilobits = 1024; M = megabits = 1,048,576; G = gigabits = 1,0737,41,824.

To represent a decimal number in the BCD system, each digit is replaced by its 4-bit binary equivalent. Thus, the number 729 in BCD is:

7 2 9

0111 0010 1001

The BCD code is given in Table 5.2.

It is important to note that the 4-bit binary numbers 1010 through 1111 that represent the decimal values 10 through 15 are invalid in BCD.

To convert a BCD number to decimal, simply substitute the decimal equivalent of each 4-bit group. The BCD number 1001 0100 0110 in decimal is 946.

A special form of BCD code is used in computers and data communications systems. It is a 7- or 8-bit code that is used to represent not only numbers but also letters (both uppercase and lowercase), special symbols, and control functions. This code is called the American Standard Code for Information Interchange, or ASCII (pronounced "ask-key").

The following are examples of ASCII:

lowercase letters, the digits 0 through 9, punctuation marks, common mathematical symbols, and many special two- and three-letter codes. The special codes are known as control codes. They are used to indicate the start and end of a string of characters or to initiate special operations. Some examples follow:

STX—Start of text sequence
EOT—End of transmission of a string of characters
BEL—Ring a bell
DEL—Delete
LF—Line feed
CR—Carriage return

These codes not only represent alphanumeric data but can also make things happen in a printer or computer.

The main use of ASCII is in data communication. Computers use ASCII to "talk" to their peripheral units, such as printers, or to one another. A common example is a personal computer that receives data via a modem from the Internet. Another example is the data sent from a computer to a laser printer. ASCII is the communication code for text.

Hexadecimal Notation

Hexadecimal notation is a way to represent binary values with numbers and letters in an effort to make data easier to remember, and to reduce the errors normally associated with writing or reading long strings of 1's and 0's. The hex code is just an extension of the BCD code, with the decimal values from 11 to 15 represented by the letters A through F. See the following table.

Hexadecimal Notation (Continued)

As an example to convert the binary number 101000110101100 to hex, you divide the word into 4-bit groups starting on the right and then replacing each with the hex codes. In this case, the hex code is A35C.

Parallel and Serial Data

It is frequently necessary for digital devices to communicate. Someone using a computer may have to send data to a printer. Or two people using personal computers may have to communicate over a local area network (LAN). To accomplish either of these objectives, one must transmit binary data from one circuit to another. This is done in one of two ways: parallel transmission or serial transmission.

Parallel Data

When the parallel method is used, all bits of a binary word or number are transmitted simultaneously. Figure 5.4 shows an 8-bit word being transferred from logic circuit 1 to logic circuit 2.

A *bus* is a set of parallel data lines over which digital data is transferred. A data bus can have any number of data lines as required by the application. However, the main characteristic of a bus is parallel data transfer. In physical form, a bus is usually implemented on a connector, with lines of copper on a printed circuit board or with a ribbon cable with one wire per bit.

Because all bits are transmitted at the same time over a parallel bus, data movement is extremely fast. The main benefit of parallel data transmission is its high speed. With high-speed logic circuits, a binary word can be transferred from one point to another in as little as several nanoseconds. Parallel data transmission over buses in computers takes place at rates up to several hundred megahertz. It is not uncommon to see a rate of 100 million bits per second (Mbps)

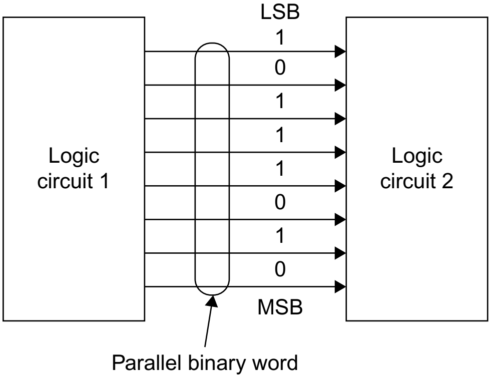

FIGURE 5.4 Parallel binary data transfer over bus.

on a personal computer data bus. On long buses, data rates are slower because the stray inductance and capacitance of the cable typically distorts the data and slows the transmission speed.

Although parallel transmission is fast, it is expensive, because there must be circuitry for each bit on both the sending and receiving ends. There must be one wire per bit in a cable plus a separate ground wire. This increases the complexity and thereby the cost of the circuitry.

Serial Data

The other method of moving binary data from one point to another is serial transmission. In the serial method, the bits of a word are transmitted one at a time, or sequentially. Figure 5.5 shows the waveform of an 8-bit serial binary word. This is the voltage that you would monitor at the single output of the circuit generating the word. It is the waveform that an oscilloscope would display. Each bit occurs for a fixed time interval such as 1.5 milliseconds. Thus, it takes $1.5 \times 8 = 12$ milliseconds (ms) to transmit an 8-bit word.

The speed of data transmission is measured in bits per second (bps). That figure can be calculated from the expression:

$$\text{bps} = \frac{1}{t}$$

Here, t is the time for 1 bit. In Figure 5.5, 1 bit takes 1.5 μs. The speed of the data, then, is

$$\text{bps} = 1 \div (1.5 \times 10^{-6}) = 666{,}666.7\,\text{bps or } 666.7\,\text{kbps}$$

If you know the speed in bps, you can calculate the bit time (t) by rearranging the formula:

$$T = \frac{1}{\text{bps}}$$

Assume a data rate of 14,400 bps. The bit time is 69.4 μs.

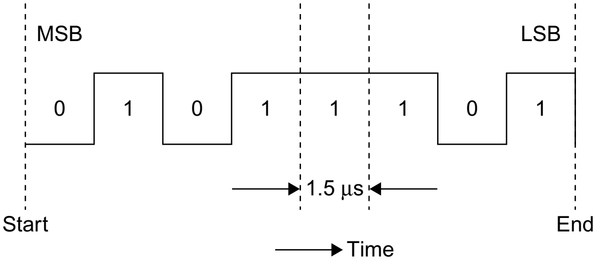

FIGURE 5.5 Serial data transfer where 1 bit occurs after another in time.

As seen in Figure 5.5, the MSB is transmitted first. Depending on the system used, however, the LSB can be sent first. In any case, the speed of transmission depends on the number of bits in the word and the duration of each bit. It is this longer transmission time that is the primary disadvantage of the serial method. However, although serial transmission is slower than parallel transmission, it is perfectly suitable for many applications. Common data rates are in excess of millions of bits per second. Data rates of more than 10 Gbps are common.

The main benefits of the serial method are its simplicity and low cost. Only a single line rather than multiple lines is needed to interconnect the equipment. In addition, only one set of sending and receiving circuits is needed. All data transmissions by copper cable or fiber optical cable exceeding about 100 Mbps are made by the serial method. All wireless data transmissions are serial.

DIGITAL LOGIC ELEMENTS

Digital logic elements are the basic circuits that are used to process the binary data. The logic element has one or more binary data inputs to be processed. The logic element processes or manipulates the binary input signals in a fixed way and generates an appropriate output signal. The output is a function of the binary states of the inputs and the unique processing capability of the logic element. The logic element "looks" at the binary input signals, and then makes a decision and generates an appropriate output. There are five elementary logic circuits: inverter or NOT, AND, OR, NAND, and NOR. These functions are performed by logic elements known as inverters and gates.

You need not be concerned with the inner workings of these logic elements. Instead, your primary concern is with the basic logic functions. Needless to say, the gates and inverters are inside every microcomputer and digital integrated circuit.

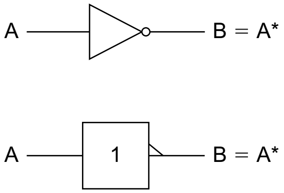
Inverter

The inverter has a single input and a single output. The logic function performed by an inverter is *inversion*. The output of the inverter is simply the inverse, or opposite, of the input. Because binary signals can assume only one of two different states, either 0 or 1, the inverter generates a 0 when the input is a 1, and a 1 when the input is a 0.

Two common symbols used to represent an inverter are shown in Figure 5.6. The input and output are given names, which are usually letters of the alphabet.

There are a variety of ways to express the operation of various logic functions. One way is to use Boolean algebraic expressions. A Boolean expression is a simple mathematical or algebraic formula that expresses the output in terms of the input. The Boolean expression for the inverter is:

$$B = A^*$$



A	B
0	1
1	0

FIGURE 5.6 Logic symbols for inverter and truth table.

This equation is read, “B equals not A.” The asterisk means NOT or inversion. What this expression is telling you is that if the input is A, the output, B, is not A.

Another method of expressing the function of a logic element is a truth table. This is simply a table listing all possible combinations of the inputs and outputs of a logic element. Figure 5.6 also shows the truth table for an inverter. There are only two possible inputs, 0 and 1, and the corresponding outputs. A truth table completely defines the operation of a logic element.

AND Gate

A gate is a circuit that has two or more inputs and a single output. The gate generates a binary output that is a function of the states of the inputs and the nature of the gate itself.

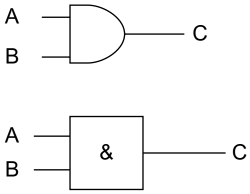
The type of gate determines how the binary inputs are processed. The two basic logic gates are the AND gate and the OR gate. An AND gate is a logic circuit that generates a binary 1 output if all of its inputs are binary 1’s. Otherwise, the circuit generates a binary 0. All of the inputs have to be binary 1 for the AND gated to produce a binary 1 output. If any one of the inputs is a binary 0, the output is binary 0.

Figure 5.7 shows the logic symbols used to represent an AND gate. Letters of the alphabet are used to represent inputs and outputs. There may be more than two inputs, but there is only one output.

As with the inverter, the output of the AND gate can be expressed in terms of the inputs with a Boolean expression. The Boolean expression for an AND gate is:

$$C = AB$$

This equation is read, “C equals A and B.” Parentheses also can be used to separate the inputs; for example, $C = (A)(B)$.



A	B	C
0	0	0
0	1	0
1	0	0
1	1	1

FIGURE 5.7 Logic symbols for AND gate and truth table.

The truth table for a simple two-input AND gate is also shown in Figure 5.7. Note that the output C is a binary 1 when both inputs are binary 1's. At all other times, the output is binary 0. With two inputs, there are a total of four different input combinations ($2^2 = 4$). With three inputs, there are $2^3 = 8$ possible input combinations for an AND gate. These inputs are the binary numbers 000 through 111.

One of the most common applications of an AND gate in digital circuits is gating. Gating simply refers to the use of one binary signal to control another. A two-input AND gate is most often used as a control gate. One input signal is the control that either keeps the other input signal from passing through to the output or allows it to pass.

Figure 5.8 shows the inputs and output of a typical control gate. Note that multiletter names called *mnemonics* are used instead of single letters to designate the input and output signals. The ENB or enable input represents the control signal. As long as the ENB input is a binary 0, the output is a binary 0. The gate is said to be inhibited because nothing more than a binary 0 output occurs.

When the ENB control input is a binary 1, the gate is enabled. At this time, the main input signal, CLK for clock, is allowed to pass through to the output BST. CLK is a periodic clock signal that switches repetitively between the binary 0 and the binary 1 levels at a fixed frequency. The output of the AND gate follows the CLK input as long as the ENB control input is a binary 1.

OR Gate

Another commonly used logic gate is the OR circuit. Like the AND gate, the OR gate has two or more inputs and a single output. The OR gate generates a binary 1 if any one or more of its inputs are binary 1. The only time the output of an OR gate is binary 0 is when all its inputs are binary 0.

FIGURE 5.9 Logic symbols for OR gate and truth table.

The symbols used to represent an OR gate are shown in Figure 5.9. Letters of the alphabet are used to designate the inputs and outputs. Using these designations, the Boolean output expression for the OR gate is:

$$D = E + F$$

This equation is read, "D equals E or F." In this Boolean expression, the plus sign designates the OR function. In a Boolean logic expression, the plus sign does not mean addition. In Figure 5.9, the mathematical symbol ≥ (greater than or equal to) is used to designate the OR logic function. The truth table for an OR gate further defines its operation. The output D is a binary 1 when input E or input F or both are a binary 1. Like an AND gate, an OR gate can have any number of inputs.

NAND and NOR Gates

The AND and OR logical functions are basic to all digital systems. Although these functions are implemented with AND and OR gates, a variation of these gates is even more widely used. These are NAND and NOR gates, which are a combination of either an AND gate or an OR gate and an inverter. These gates are more flexible in their application when they are used together.

A NAND gate can be made with an AND gate followed by an inverter. Figure 5.10 shows this circuit configuration. Note the two special symbols in Figure 5.10 used to represent the logical NAND function. The truth table is also given.

A NAND gate can perform all of the gating and detection functions mentioned earlier for an AND gate. The only difference is that the output is inverted.

The other widely used digital logic element is a NOR gate. A NOR gate is a combination of an OR gate followed by an inverter (see Figure 5.11). The symbols used to represent the NOR logic function are also shown. The output of a NOR gate is simply the complement of the output of an OR gate, as shown by the truth table. An XOR actually is a 1-bit binary adder.

Exclusive OR Gate

A variation of the OR gate is the exclusive OR, usually designated XOR. Its symbols are given in Figure 5.12. The truth table is also shown. Note that the

circuit only produces a 1 output if the two inputs are opposite. The output is 0 if the two inputs are the same.

An inverted XOR or XNOR has the symbols and truth table shown in Figure 5.12. It is useful as a 1-bit comparator since the output is 1 if both inputs are the same.

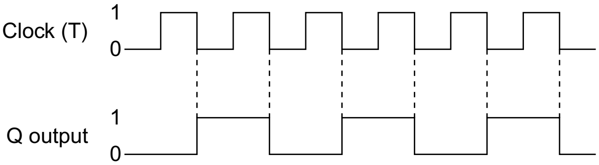

FIGURE 5.14 Toggling T input on JK flip-flop causes it to change states, producing frequency division by 2.

Flip-Flops

A flip-flop (FF) is another basic building block of electronics. It is essentially a circuit that stores 1 bit of data. The circuit has two states—set and reset. If the FF is storing a binary 1, it is set. If it is storing a binary 0, it is reset. Figure 5.13A shows the basic block diagram of a reset-set (R-S) FF. The inputs are set (S) and reset (R). The two outputs Q and Q* are complementary. You apply an input to the appropriate input to set or reset the FF.

A D-type flip-flop is shown in Figure 5.13B. It has a D or data input and a clock (T) input. When the clock occurs, the FF is either set or reset depending on the value of the D input. The D FF is used to store 1 bit of data.

Another type of FF is the JK, shown in Figure 5.13C. It has J and K inputs that correspond to S and R inputs, respectively. It also has a clock or T input that performs the set or reset operations. To store a binary 1, you make J = 1 and K = 0. When a clock input occurs, the FF is then set or reset.

The T input also causes the state of the FF to toggle or change state when a clock transition occurs (see Figure 5.14). This feature is used to produce frequency division by 2 as shown. The output is a square-wave half the frequency of the T input. Additional JK FFs can be cascaded to produce frequency division by the power of 2 or 2, 4, 8, 16, 32, 64, and so on, as shown in Figure 5.15.

FIGURE 5.16 Storage register from one word consists of FFs. It also has clock/load and clear/reset inputs.

Storage Registers

A storage register is a place to store a binary word or number. It is made up of 1 FF per bit. An 8-bit register stores bytes and has 8 FFs. Figure 5.16 shows a register with eight inputs and eight outputs. Most registers also have a clock input also called LOAD or STORE that determines when the input data is stored. Some also have a CLEAR or RESET input that puts all the FFs in the binary 0 state.

Shift Registers

A shift register (SR) is like a storage register, but the bits stored there may be shifted from one FF to the next as each clock pulse occurs. Figure 5.17A shows how serial binary data is shifted into the SR for storage. As new data

is shifted in, the existing data will be shifted out and sent to another circuit. Figure 5.17B shows data being shifted out as binary 0's are shifted in.

Shift registers are often used for parallel-to-serial and serial-to-parallel conversions. A serial-to-parallel conversion is shown in Figure 5.18A. The SR initially contains all binary 0's. Then serial data is shifted in and the output is taken in parallel from the FF outputs. For parallel-to-serial conversion, a binary word is initially stored in the register. Then the word is shifted out as the clock pulses occur (see Figure 5.18B).

Counters

As its name implies, a counter is a circuit that counts input pulses. Counters are made of multiple cascaded FFs, and they are sometimes accompanied by logic gates. As the input pulses occur, the binary number stored in the counter FFs tells how many pulses have occurred. The frequency divider shown in Figure 5.15 is also a 4-bit counter. It can count from 0 (0000) to 15 (1111).

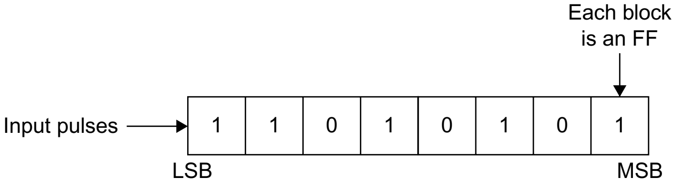

FIGURE 5.19 Counter storing binary value equal to number of input pulses that occurred.

If all FFs are initially reset to 0, then 10 pulses occur, and the FFs from A to D would be storing 0101 from left to right. The right-most FF (D) is the MSB, so you read the counter as 1010 or the binary equivalent of decimal 10.

Binary counters can store numbers up to $2^N - 1$, where N is the number of FFs. For example, an 8-bit counter would count from 00000000 to 11111111 or $2^8 - 1 = 256 - 1 = 255$.

Figure 5.19 shows a counter where 178 pulses have occurred, so the counter stores the number 10101011 that is the binary equivalent of 179.

Another popular form of counter is the BCD version that counts from 0000 to 1001 or 0 through 9. BCD counters are used to keep track of decimal quantities in binary form. BCD counters can serve as frequency dividers as well. Each divides by 10.

COMMON LOGIC CIRCUITS

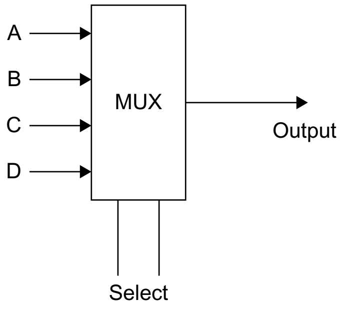
There are several types of logic circuits that occur again and again in digital equipment. The counters and registers just described are good examples. A few others that you may encounter are described in this section. Remember that these circuits can be made from individual gates and FFs in IC form. You can also buy them in IC form already wired for their specific function. But mostly these circuits appear as a collection of circuits inside some larger IC.

Multiplexer

A multiplexer or mux is a circuit with two or more inputs and one output (see Figure 5.20). Here there are four inputs and one output. Two other inputs are used to select one of the inputs to appear as the output. The four selected inputs are 00, 01, 10, and 11. In the figure, note which input is routed to the output with each input select code. Multiplexers can have as many inputs as needed.

Demultiplexer

A demultiplexer or demux is the opposite of a mux. It has one input and multiple outputs. Like the mux, select inputs specify which of the output lines the input is connected to.



Select	Input at output
00	A
01	B
10	C
11	D

FIGURE 5.20 Digital multiplexer (mux) that selects one of four inputs to appear at the single output.

Decoder

A decoder is a circuit that can detect a specific binary code. In its simplest form, it is just an AND gate, as shown in Figure 5.21A. If the input 0110 appears at the inputs, the AND gate will have all its inputs at binary 1, so the output will be binary 1 indicating that it is detecting the desired input. For any other 4-bit input, the output will be binary 0.

Decoders can also be made to detect all states of a given binary input. For example, a 4-bit decoder like that in Figure 5.21B looks at the 4-bit inputs and decodes all states from 0000 to 1111. If the input is 1000, the 8 output is binary 1 and all other outputs are 0.

Comparators

A comparator takes two binary words as inputs and compares them. If the two inputs are equal, a binary 1 output occurs. Otherwise, if the two inputs are different, the output is 0. Some comparators have outputs that can tell if one input is larger than or smaller than the other.

Arithmetic Circuits

Digital logic does a good job of basic arithmetic functions like add and subtract. The basic computing element is called an arithmetic logic unit (ALU). It does binary addition and subtraction. It can also perform basic logic operations such as AND, OR, or XOR on two binary input words. Circuits for multiplication and division are more complex, but are common in digital computers.

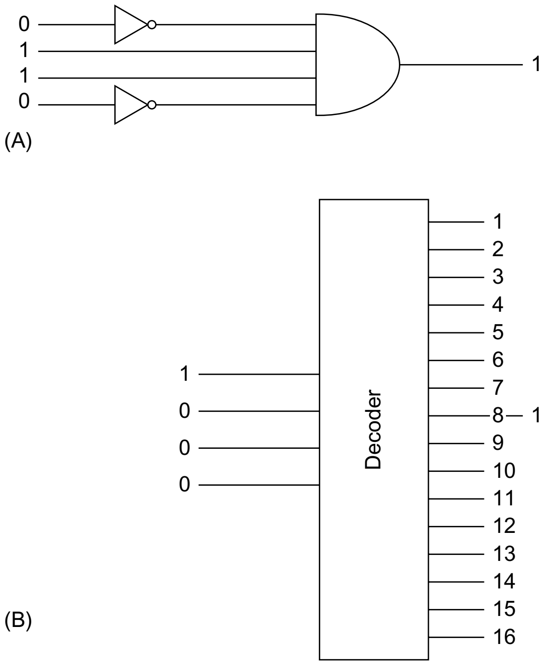


FIGURE 5.21 Decoders. **(A)** 1-AND gate decoder that identifies input 0110. **(B)** 4-to-16 decoder that identifies 1 of 16 different 4-bit input values.

DIGITAL MEMORIES

Digital memories are semiconductor circuits that store binary data. You have probably heard of the terms RAM and ROM as they apply to personal computers. These are the two main types of memory, random access memory (RAM), and read-only memory (ROM).

RAM

The random access memory is one in which you can access hundreds, thousands, or millions of binary storage locations. You can store one binary number or word in each location or read the data out of the location. Each location is referred to by a unique binary number called the address. You send the memory an address and activate the selected location. Then you can read data from the location or write data into that location. RAMs therefore are what we call read-write memories.

Figure 5.22 shows the concept of a RAM. It has eight locations for 4-bit words. To address eight locations you need a 3-bit address ($2^3 = 8$). When you apply the address to the address decoder, the decoder activates the desired location. In the figure you see that the binary number 1001 stored in location 011 is being accessed and read out.

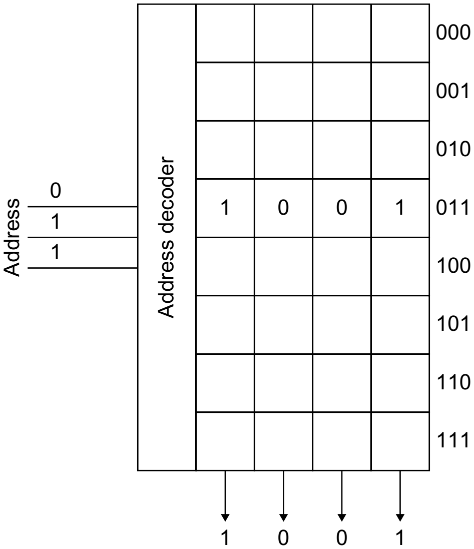

FIGURE 5.22 Basic concept for random access memory (RAM). Address selects one of eight storage locations. Then data may be read from that location or data stored in it.

Most memories are large today. We talk about megabytes (MB) or millions of bytes of data or gigabytes (GB) or billions of bytes of data in a modern PC. Embedded controllers will have fewer locations, usually in the thousands of bytes (KB) or perhaps more in the larger systems. Storage word sizes are usually 8 (bytes), 16, 32, or 64 bits.

There are two ways to make a RAM. The first way is just to build one FF for each bit to be stored. The basic set-reset FF described earlier is the basic storage circuit (see Figure 5.23A). Memories using this type of circuit are called static RAM or SRAM. They are called static because once you store the bit in the FF, it stays there as long as power is applied to the circuit.

The other form of RAM is called *dynamic RAM* or DRAM. The basic storage circuit is a capacitor as shown in Figure 5.23B. If you charge the capacitor, it is storing a binary 1. If the capacitor is discharged, a binary 0 is being stored. A MOSFET is used as a switch to access the capacitor. If the MOSFET is turned on by an input address on the gate, it connects the capacitor to the data line, where it may be read out or where a new bit may be stored. When the MOSFET is turned off, the capacitor is isolated and just stores the bit.

The reason why the term *dynamic* is used for this type of RAM is that the charge on the capacitor will leak off very quickly. The capacitor is very small and millions of them are made on a tiny chip of silicon. For this reason, the capacitor has to be recharged every so often so that the data is retained. This is called a refresh operation and it usually occurs every 2 milliseconds or so.

Comparing SRAM and DRAM, you should know that SRAM is the faster of the two in that you can store data or read data out faster than you can with a

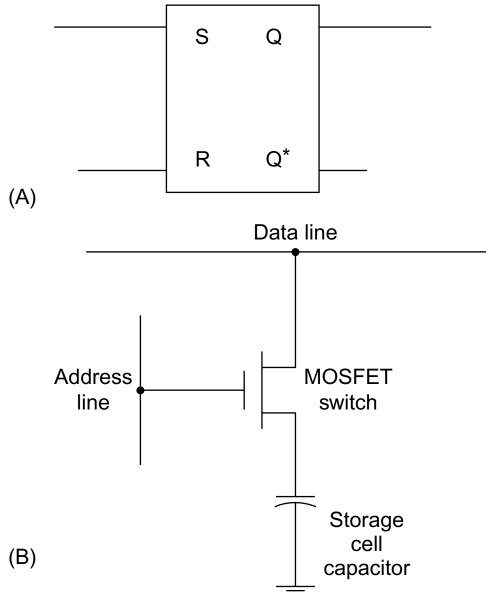

FIGURE 5.23 RAM storage cells. **(A)** RS FF for SRAM. **(B)** Capacitor cell for DRAM.

DRAM. The downside is that the SRAM is more complex and takes up more space on the chip, and thus costs more. The DRAM is slower but not much. Its advantage is that you can put more storage cells on a chip, making them cheaper. The need to refresh is a downside but easy to live with, as all the refresh circuitry is on the chip and the process is transparent to the user.

Just keep in mind a key fact. RAM is fast and reliable, but it loses all data if the DC power to the memory circuit is removed. All data is erased. RAMs are therefore said to be volatile.

ROM

Read-only memories are nonvolatile memories. Once you store data in them, they retain the data when power is removed. In some ROMs, you can change the data stored there. Incidentally, all ROMs are random access in that you can go to any desired location to read or maybe write data.

There are several categories of ROM. The older types are called masked ROM, where the mask refers to the actual wiring of the ROM to permanently fix the data in the circuitry when it is made. The storage cells are essentially a MOSFET matrix where each MOSFET is permanently turned on or off to store 1 or 0. No changes are possible. Later a programmable ROM or PROM was developed. It used a special MOSFET that could be programmed on or off. You could then erase the programming by shining ultraviolet (UV) light

on the chip for a short time. Then the PROM could be reprogrammed. These are no longer used.

Most ROMs today are what we call electrically erasable programmable ROMs or EEPROMs or E^2PROMs. The storage element is a MOSFET that you turn off or on with a programmable voltage (see Figure 5.24). The MOSFET retains that state until it is electrically changed.

The main problem with EEPROMs is that they are slow to erase and reprogram. But today we have a special version of EEPROMs called flash memories. These are also EEPROMs, but they actually are almost as fast as RAMs for reading and writing data. Yet they are nonvolatile.

You will hear of two types of flash memory—NOR and NAND. NOR flash is used to store programs for microcontrollers. It can only be erased on large block sizes and not individual cells. NAND flash is faster and you can erase individual memory locations. The NAND flash is gradually replacing the NOR flash in many applications.

Flash memory has become so popular it is used in almost every electronic product today. MP3 players and iPods store music in flash memory. Cell phones store phone numbers, digital cameras store photos, and in embedded controllers, the flash usually stores the program that tells the processor what to do. And, let’s not forget the flash drive or “thumb” drive as it is called. These devices with a USB connector can store many gigabytes of data and are very inexpensive. Flash memory is also used to make solid-state drives (SSDs) that are the equivalent of the hard disk drives used in PCs and laptops. They are still expensive, but as prices decline, you can look for more SSDs to replace conventional mechanical/magnetic hard drives.

PROGRAMMABLE LOGIC DEVICES

There are two ways that digital devices are built today. The most common is to use an embedded controller or microcomputer. This is a single-chip computer that you can program to do whatever digital function you want. Most electronic products have at least one embedded controller at the heart of their design.

In some cases, the embedded controller is not fast enough to do the job. One way to make the circuitry is to use individual logic circuits such as gates, flip-flops (FFs), counters, and so on. That is the way it used to be done. Now, if you need fast custom digital logic, you build the circuit with a programmable logic device (PLD). A PLD is an IC that contains a mix of gates, FFs, and other circuits that can be programmed to implement any digital function. The programming is usually done on a computer and a file is created. The file is then downloaded to the PLD, where it is stored in a RAM or ROM. The file in the memory determines how the unique circuit is formed.

There are three basic types of PLDs: simple PLDs, complex PLDs, and field programmable gate arrays (FPGAs). The SPLDs are small devices for simpler digital circuits. The most common types are called programmable array logic (PAL), programmable logic arrays (PLAs), and generic array logic (GAL). PROMs are also used as SPLDs. For example, the address input to a ROM is some binary number or a collection of binary inputs. These form an address to locate a specific binary word stored in that location. When that particular selection of input bits occurs, it forms the address that identifies the memory location where the desired set of output responses is stored. This form of SPLD is also called a look-up table or LUT.

The other SPLDs are essentially a set of AND and OR gates that can be programmed. They all take the form shown in Figure 5.25. You can select which inputs go to the AND gates, and/or select which AND outputs go to which OR gate inputs. A PROM has the AND array fixed and you can program the OR gates. A PAL is an SPLD in which you can program the AND inputs but the OR connections are fixed. A PLA is a PLD that lets you program both the AND inputs and the OR connections. In both PLAs and PALs, the programming is usually permanent.

A GAL is a variation of the PAL with its AND inputs programmable. The difference is that the programming can be changed. The program you develop is actually stored in flash memory. The flash memory cells send the programming bits to the various AND and OR gates telling them what logic to implement. You can then erase it and reprogram if you want or need to. GALs also have one or more FFs associated with the logic gates, so you can store bits or actually build counters and registers by programming.

CPLDs are complex PLDs similar to SPLDs, only larger. They contain more gates and flip-flops so that very large logic projects can be built on a single chip. A typical CPLD is really just a large collection of PALs or GALs that can be individually programmed and then connected together with a large

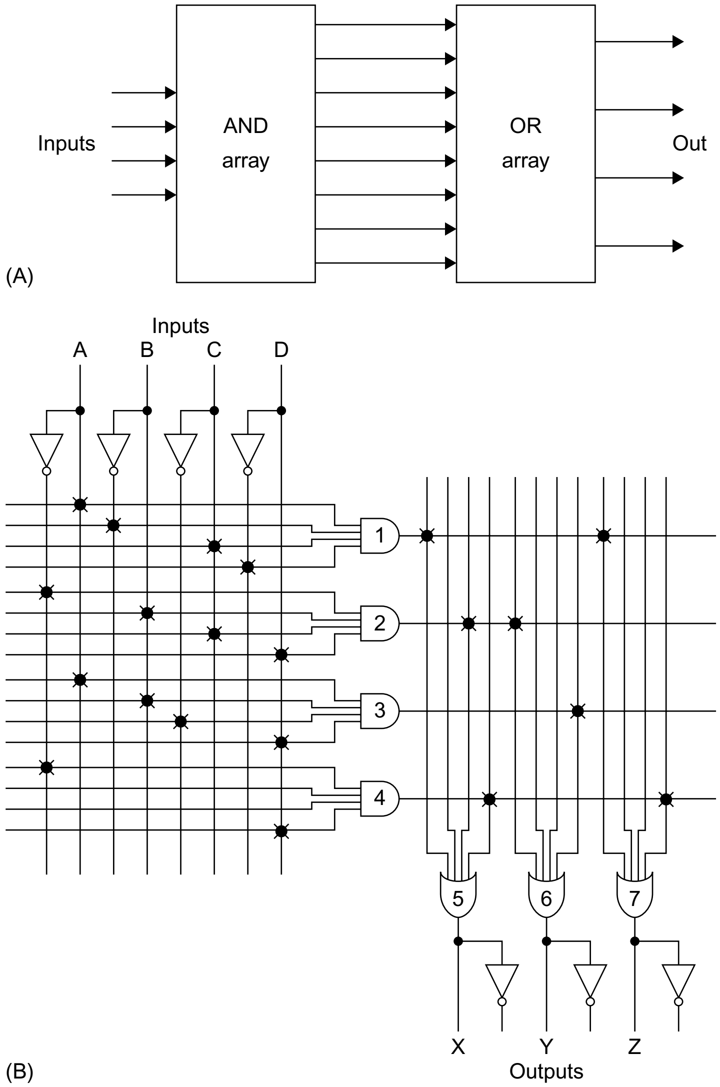

FIGURE 5.25 PLD concept. **(A)** Block concept of programmable AND and OR gate arrays. **(B)** Simple circuit of PLD showing programming by dots on AND and OR gate arrays.

interconnect matrix. Input/output (I/O) circuits also provide inversion if needed or extra power to drive external circuits. Again, flash memory is used to store the programming.

The largest and most flexible PLD is the field programmable logic array or FPGA. It has become the most popular and common way to implement digital equipment other than a microcontroller. FPGAs are large chips that contain thousands of logic circuits. The largest devices have millions of gates and other circuits. Most FPGAs are programmed by storing a bit pattern in the SRAM cells inside. These cells tell the logic circuits what configuration to take and what functions to perform. If you turn the power off, the programming goes away and all you have is a dumb FPGA with no logic interconnections or functions. When you power up an FPGA, the desired program, usually from a flash memory, or a computer loads the RAM cells with the program, thereby enabling the FPGA to perform its desired function.

The logic inside an FPGA is essentially thousands of look-up tables (LUTs) that can be individually programmed. Each LUT has its own program memory block as well as one or more FFs and I/O circuits. The LUTs may also be interconnected to one another by programming. With this arrangement virtually any digital logic operation can be programmed. You can even make your own custom computer with an FPGA, for example.

There are about a half-dozen companies that make PLDs. The two oldest and largest are Xilinx and Altera. Both have extensive lines of CPLDs and FPGAs.

DATA CONVERSION

The term *data conversion* refers to the translation of analog signals into digital form and vice versa. While it used to be an all-analog electronics world, today it is virtually all digital. We still have analog signals such as voice, video, radio waves, and sensor voltages, but mostly we process, store, and transmit data by digital means. For that reason, circuits that perform these conversions are critical to virtually all electronic applications. All cell phone voice is digital, all modern TV is digital, and sensor outputs are captured and processed in digital form. It is difficult to name a product today that does not use some form of data conversion.

Analog-to-Digital Conversion

The process of converting an analog signal into a digital one is called analog-to-digital conversion, and it is performed by an analog-to-digital converter (ADC). The process, also referred to as sampling, is illustrated in Figure 5.26. The ADC looks at the analog input and periodically takes a sample of the voltage at that instant, captures it, and then converts it into a proportional binary number. We say that we are digitizing the signal. The sample points are shown by the dots on the analog curve. The binary value of the sample is shown to the right of the curve. The conversion process actually results in a sequence of binary numbers that represent the analog waveform. These values are usually stored in a RAM or transmitted to other circuits as shown in Figure 5.27. Note the symbol for an ADC.

Digital-to-Analog Conversion

To recover the original signal, we put the data sequence previously captured by the ADC into a digital-to-analog-converter (DAC) (see Figure 5.28). The output is a version of the analog signal. The DAC output is not a perfect reproduction, but just an approximation. This is shown in more detail in Figure 5.29. Each binary input results in a constant voltage output from the DAC during the sample period. The result is a stepped approximation to the original signal. The rate at which the binary data is sent to the DAC must be the same as the sampling interval to recover the original frequency information in the signal.

Resolution and Sampling Interval

The key to good data conversion is to use greater resolution and faster sampling rates. Resolution refers to the number of bits used in the data conversion.

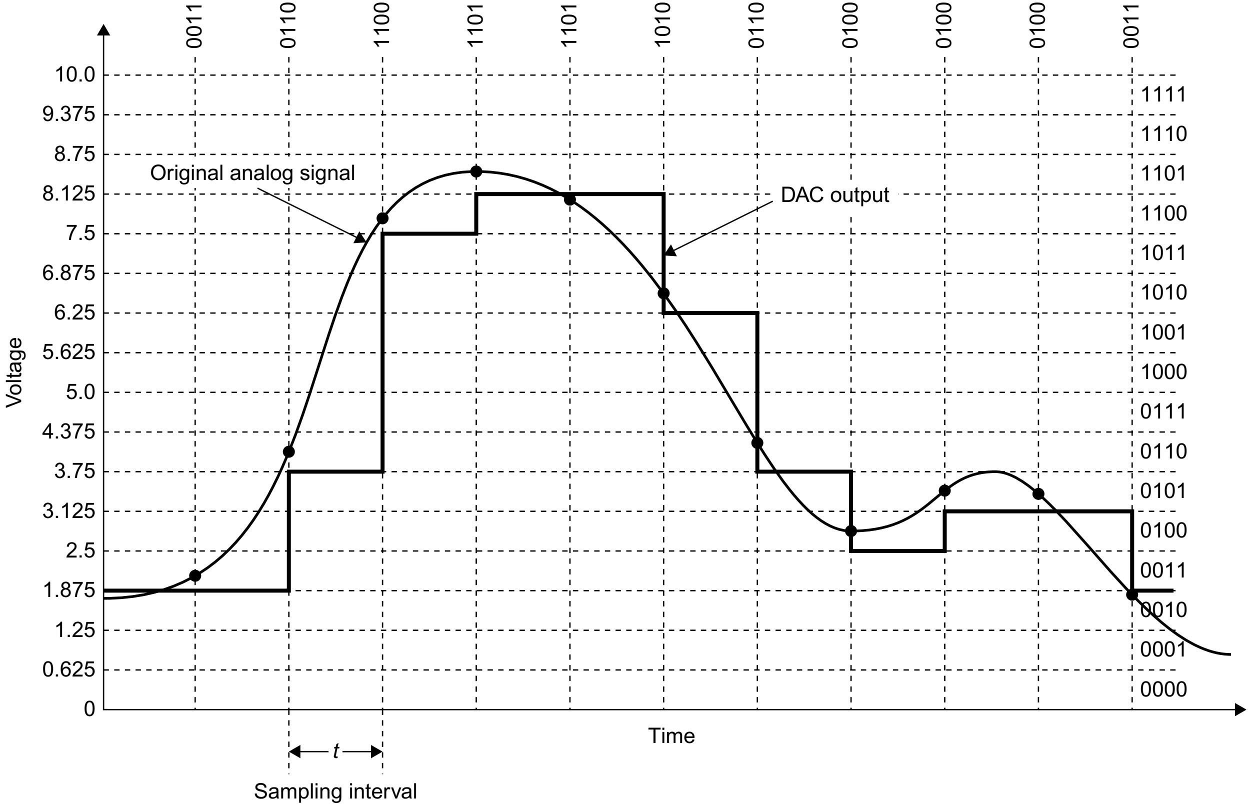

FIGURE 5.29 DAC output is stepped approximation to original analog signal.

In Figure 5.27, only 4 bits are used, so the resolution is poor. The voltage range is only divided into 16 intervals, meaning that amplitude variations at less than 0.625 volt are missed. This problem can be corrected by using more bits. ADCs are available in many bit sizes. The most common are 8, 10, and 12 bits, but 14 and 16 bits are available. Some methods of ADC produce resolutions of 20 to 26 bits. The result is a finer conversion of amplitude detail. As an example, if the 0- to 10-volt range in Figure 5.27 was sampled with a 12-bit ADC, the individual smallest voltage increment that can be detected is $10/2^{12} = 10/4096 = 2.44\,\text{mV}$ instead of the 0.625 volt in the figure.

Another critical specification is sampling rate. To retain all the frequency detail in a signal, the sampling rate must be at least twice the highest frequency in the signal. This is called the Nyquist criterion. For example, when digitizing music with a frequency range of 20 Hz to 20 kHz, the sampling rate must be at least double the 20-kHz frequency. In most systems, a rate of 44.1 kHz or 48 kHz is used.

ADCs with sampling rates to several hundred megahertz are commonly available, meaning that even radio signals can be digitized.

INTRODUCTION

Whenever you hear or see the word *microcomputer*, you probably think of a personal computer. A personal computer is, of course, one type of microcomputer. But you may not be aware of other forms of microcomputers. For example, do you know that almost every piece of electronic equipment you own or use has a microcomputer in it? This type of microcomputer is called an embedded controller. It is usually a single integrated circuit that performs all of the basic functions of a computer but is dedicated to a specific task. Such micros (*micro* is short for microcomputer) are in TV sets, stereo receivers, microwave ovens, CD players, DVD players, cell phones, blenders, copiers, and most other types of electronic devices. You will find them in your car (several of them), your iPod, your bathroom scale, gasoline pumps, and dozens of other things you use every day. Microcomputers do indeed make your day—you cannot live without them.

CONCEPTS AND DEFINITIONS

A microcomputer is a small digital computer that can take several different forms. It can be a single integrated circuit, or it can be a module made up of several integrated circuits on a printed-circuit board.

doi: 10.1016/B978-1-85617-700-9.00006-0

The two most common types of microcomputers are the embedded microcontroller and the personal computer. One special type of microcomputer is the programmable logic controller (PLC) used for industrial control (Chapter 12).

The larger microcomputers, such as personal computers, are made with a microprocessor. A microprocessor is a large-scale integrated circuit that contains most of the digital logic circuitry usually associated with a digital computer. This logic circuitry is referred to as the central processing unit (CPU). A microprocessor is a single-chip CPU.

Another common micro is called a *core*. A core is a microprocessor or microcomputer integrated with some other circuits. The core is made on the same silicon chip as a cell phone or a security device. Today multicore micros are common. Two or more cores are used to get more processing power.

Embedded microcontrollers are complete micros on a single chip, including the CPU, memory, and input/output circuits. But in all cases, a microcomputer is an assembly of digital logic circuits, such as gates and flip-flops, that is used to process data. It is sometimes referred to as a *data processor*, or simply *processor*.

Data, of course, refers to the binary numbers and words the processor works with. Processing refers to the way the data is manipulated or handled. Types of processing include arithmetic, logic, sorting, translating, editing, counting, and searching. Any action taken on the data is called processing. Processing normally implies that the data is changed in some way or is used to create new data. Data that is not processed as suggested above is dealt with in other ways. Four common ways are storing, retrieving, input, or output. The data is not changed by any of these techniques.

Storing data means putting it in a safe place, like a semiconductor memory or disk drive, where it can be accessed later. *Retrieving*, of course, is the opposite of storing, or going to get the data for reuse.

Input means taking data into the computer to be stored or processed. *Output* means sending the data from the computer to some external device. Input and output (I/O) are ways to transmit data from one place to another.

Another feature of a microcomputer is its *decision-making* capability. During processing, the computer can make decisions and alter its sequence of operation. In other words, the computer can “make up its mind” based on the state of the data or outside conditions.

For example, the computer can tell if a number is less than, greater than, or equal to another. It can choose among alternative courses of actions or say yes or no, true or false, if given enough input facts.

Another major application of computers is *control*. Computers can be used to actuate relays and solenoids or turn lights and motors off and on (see Figure 6.1). In control applications, the computer actually determines when external devices are turned on or off. The computer serves as an electronic clock to time various operations. One example is the embedded single-chip microcontroller inside a microwave oven or a washing machine. Another example is a programmable logic controller (PLC), a special type of microcomputer used

in industrial applications, that is commonly used to sense, sequence, and time operations in a factory.

The most important thing to remember is that the control is automatic. The micro knows when to perform the various operations that it has been assigned because it has been programmed to do so.

In order to implement certain control applications, the micro must also perform a monitoring function. The micro "looks at" the process or devices being controlled to see what is happening. For example, the computer can monitor switch closures to determine physical state or position, pressure, and many other parameters. Transducers (sensors) convert the monitored physical characteristics, such as temperature or light level, into electrical signals that the computer can understand and respond to (see Figure 6.2). In most microcontrollers or PLCs, the controlled output change takes place only if a specific

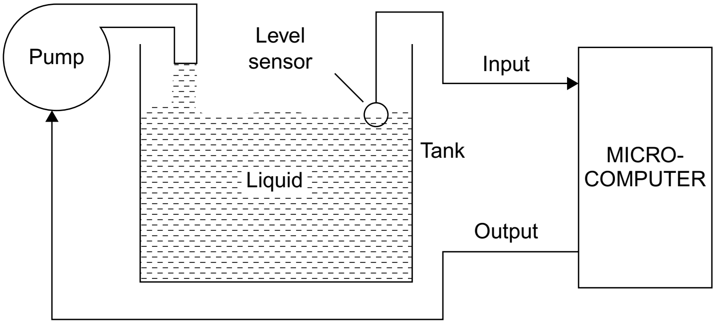

FIGURE 6.3 Controlling liquid level in a tank automatically with a micro.

input condition is sensed or not sensed. For example, if a temperature sensor indicates that the temperature has risen to a specific level, the computer will turn on a cooling fan.

Micros sometimes change the control function in response to one or more of the inputs they are monitoring. For example, if the micro senses that the liquid in a tank exceeds a given level, it can automatically turn off the pump that is filling the tank. If the liquid level goes below a predetermined level, the micro detects this and automatically starts the pump (see Figure 6.3). The key point here is that the computer makes its own decisions based on the input data that it receives. The result is full automation of some process or device.

The micro's ability to monitor and control operation may be used to automate simple processes in a toy or to operate entire factories.

COMPUTER ORGANIZATION AND OPERATION

All microcomputers are made up of four basic sections: memory, control unit, arithmetic-logic unit, and I/O unit. A general block diagram of a microcomputer showing these four sections is given in Figure 6.4. These four sections communicate with one another over multiple parallel electrical conductor data paths called a bus, as shown, to process the data or perform a control function.

Note that the control and arithmetic-logic unit (ALU) are shown together in a common structure. This is the central processing unit (CPU). The CPU is, of course, usually a microprocessor.

The memory is that part of the computer where data and programs are stored. The memory in any computer may contain thousands, millions, or even billions of locations used for storing numbers, words, or other forms of information.

Two primary types of information are stored in computer memory. The first type is the data to be processed. These are the codes, numbers, letters, and other forms of data to be manipulated.

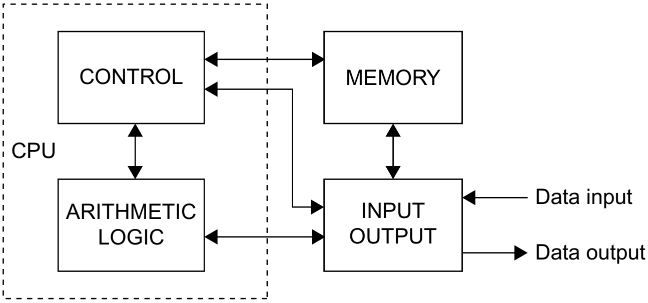

FIGURE 6.4 General block diagram of any digital computer or microcontroller.

The other type of data stored in memory is an instruction. Instructions are special binary numbers or codes that tell the computer what to do. Instructions specify the ways in which the data is to be processed. For instance, there are instructions that cause arithmetic operations to take place or data to be transferred from one place to another.

The instructions listed in a special sequence form a program. A program is a list of instructions that causes data to be processed in a unique way. A program is a step-by-step procedure that solves a problem, performs a control operation, or otherwise manipulates data according to some recipe. Programs are stored in memory along with the data that they process. In some micros there are separate memories for data and instructions. The programs that a computer uses are called software.

Data and instructions can be stored in or retrieved from memory during processing. When data is stored, we say that it is written into memory. When data is retrieved, we say that it is read from memory. A typical write operation transfers data from an analog-to-digital converter and stores it in memory. A common read operation accesses data in memory to be transferred to an LCD screen.

Now let's look at the operation of the CPU. The control unit is that portion of the digital computer responsible for the automatic operation. The control unit sequentially examines the instructions in a program and issues signals to the other sections of the computer that carry out designated operations.

Each instruction is fetched (read) from memory by the control unit, interpreted, and then executed one at a time until the program is completed. This is called the fetch-execute cycle, which is repeated on each instruction until the program runs to completion. The execution of each instruction may call for accessing one or more data words in the memory or storing a data word in memory.

The ALU is the section of the computer that carries out many of the functions that are specified by the instructions. In other words, the ALU actually processes the data. Specifically, the ALU carries out two main types of processing: arithmetic operations (such as addition, subtraction, multiplication, and division) or logic operations (such as AND, OR, complement, or exclusive OR). For example, if an add instruction is stored in memory, the control section will fetch it, interpret it, and send signals to the ALU that cause two numbers to be added.

The ALU also performs data movement operations. It can move data or instruction words from one place to another inside the CPU or it can carry out memory read/write or input/output operations. These are called load and store instructions.

A key part of the CPU associated with the ALU is the registers. Most ALUs have two or more registers. High-powered CPUs may have a group of 16 or more registers, called *general-purpose registers* (GPRs). The registers are used to temporarily store the data being processed by the ALU and the results of the computations. Other registers in the CPU store a number called an *address* where the data or instructions are stored, store the instruction being executed, or act as a stop-off place for data into or out of the CPU.

The control section, ALU, and the registers in all micros are very closely related. They operate together and are always considered as a single unit. As indicated earlier, the combination of the control and the ALU sections is called the CPU (see Figure 6.4). In addition, microprocessors are single-chip CPUs. Besides being called CPUs, microprocessors are sometimes called MPUs or *microprocessing units*. You will also see the expression μP used to refer to a microprocessor. The μ is the Greek letter mu, which means micro; the *P* means processor.

A microcomputer consists of a microprocessor (the CPU) plus external memory and I/O circuits. Or it could be an embedded controller with everything on one chip. The memory is either SRAM or DRAM for data and programs and EEPROM or flash for the program.

The I/O unit of the computer is the set of logic circuits that permits the CPU and memory to communicate with the outside world. The I/O circuits are referred to as *interfaces*. All data transfers into and out of the computer pass through the I/O interfaces.

The external peripheral devices, or *peripherals*, connected to the I/O unit are electronic or electromechanical units that are used for data entry or data display. Data is most commonly entered into the computer through an input keyboard or a disk drive.

The output data is usually displayed on a video monitor or small LCD screen. “Hard copy” on paper is created by a printer. There are a wide variety of other external input/output devices such as scanners, voice synthesizers, and barcode readers.

In an embedded microcontroller, the peripheral devices include keyboard, ADC, sensors, magnetic stripe readers, barcode scanner, and so on. Outputs go to relays, motors, lights, and liquid crystal displays (LCDs).

OPERATIONAL DETAILS

Registers and the ALU

The main circuit element in a CPU is the register. Usually the data to be processed by the CPU is taken from memory and stored temporarily in a register. Like a memory location, a register usually has a fixed length such as 8, 16, or 32 bits. But unlike a memory location, registers are often used to manipulate data as well as store it. That is, the register can alter or process the data in some way.

Examples of how a register can process data are shown in Figure 6.5. A binary word in a register can be shifted one or more bit positions to the right or left, or the register may be connected as an up/down counter so that it can be incremented (add one to the content) or decremented (subtract one from the content). A register can also be reset or cleared, thereby erasing any data in it and leaving the content zero.

Data transfers and manipulations performed on a register are initiated by individual computer instructions. For example, one instruction may cause the register to be loaded from a memory location. Another instruction may cause the word in the register to be transferred to a memory location. All data transfers are parallel, meaning that all bits are moved simultaneously from the source to the destination.

The main working register in most digital computers is called the *accumulator*. It may also be called the *A register*, *W register*, or something else.

The accumulator can hold one word whose bit length is equal to that of a memory location. An 8-bit microprocessor has an 8-bit accumulator. The accumulator is part of the ALU.

The accumulator can be loaded from memory or the accumulator content can be stored in any memory location. I/O operations with peripheral units sometimes also take place through the accumulator.

Data to be processed by the arithmetic/logic section is usually held in the accumulator. This data is fed to the ALU. The ALU is a digital logic circuit that can add, subtract, and perform a wide variety of logic operations.

The ALU is capable of processing two inputs, one from the accumulator and one from the memory of another register (see Figure 6.6). Let's assume that you wish to add two binary numbers. To do this, you first load one of the numbers (the *augend*) into the accumulator. This is done with a load-accumulator instruction that takes the number from a memory location and puts it into the accumulator. Next, an ADD instruction is executed. This causes another word (the *addend*) to be taken from memory and placed in register B. It is then added to the content of the accumulator. The sum is usually stored back in the accumulator, replacing the augend originally there.

Some microprocessors have two or more accumulator registers that share a single ALU. Two accumulators provide greater flexibility in the manipulation of data than a single accumulator. Such multiple registers simplify, speed up, and shorten a program to perform a given operation. Some sophisticated CPUs have 4, 8, 16, or even more accumulators. Usually they are referred to as GPRs or a register file. These registers can each use the ALU and act as temporary storage locations for data and the intermediate results of calculations. Instructions are provided to move data from one register to another.

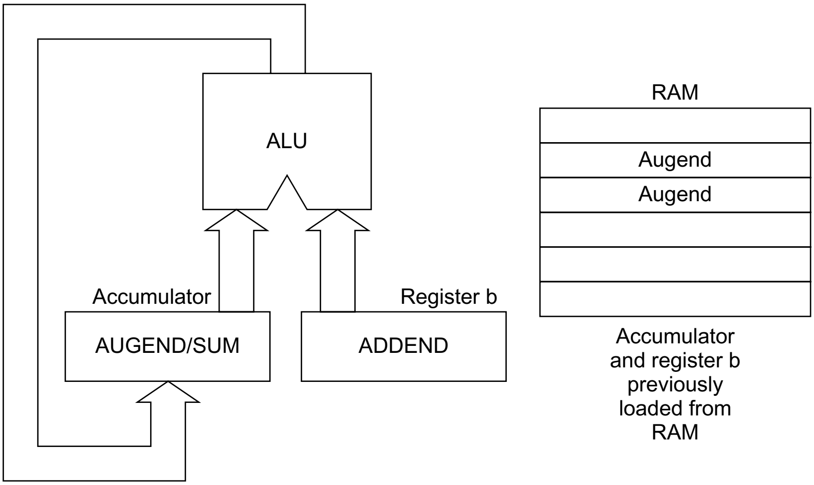

FIGURE 6.6 How ALU adds or otherwise processes two data values.

In most micros, the GPRs share a single ALU. The ALU accepts only two input words and generates a single output word. The two words to be processed by the ALU usually come from any two GPRs or any GPR and a designated memory location. The destination of the ALU output can also be one of the GPRs in some CPUs.

Control Unit

CPUs also have several other registers, including the instruction register; the program counter, also called the instruction counter; and the memory address register, also called the address buffer.

The *instruction register* (IR) is used to store the instruction word. When the CPU fetches an instruction from memory, it is temporarily stored in the IR. The instruction is a binary word or code that defines a specific operation to be performed. The instruction word is also called the *op code* or *operation code*. The CPU decodes the instruction, and then executes it.

The *program counter* (PC) is really a counter and a register. It stores a binary word that is used as the address for accessing the instructions in a program. If a program begins with an instruction stored in memory location 43, the PC is first loaded with the address 43. The address in the PC is applied to the memory, causing the instruction in location 43 to be fetched and executed. After the instruction is executed, the PC is incremented (add 1) to the next address in sequence, or 44. The instructions in a program are stored in sequential memory locations.

The *memory address register* (MAR) or *address buffer* also stores the address that references memory. This register directly drives the address bus and the memory address decoder in RAM or ROM. The MAR gets input from the PC when an instruction is to be accessed (see Figure 6.7). The MAR can also be loaded with an address that is used to access data words stored in memory. To retrieve a data word used in an arithmetic operation, the MAR is loaded with the binary word that points to the location of that word in RAM. This address is often a part of the instruction.

It is important to note that the PC and the MAR (address buffer) have a fixed length of so many bits. And that limits the amount of memory that can be accessed. For example, with a 16-bit address register, the address bus has 16 bits to address RAM and ROM. With 16 bits, a maximum of $2^{16} = 65{,}536$ words can be addressed.

There are usually two other registers, the *flag* and *stack pointer registers*. The flag or *F register* is an 8-bit register whose individual flip-flops are set and reset by the ALU as the various arithmetic and logic operations are carried out. Each flip-flop is called a flag. As an example, there are *zero* (Z) and *carry* (C) *flags*. If the accumulator content is zero after an operation is performed, the Z flag is set indicating this condition. If an arithmetic operation (addition) results in a carry from the MSB of the accumulator, the C flag is set indicating this

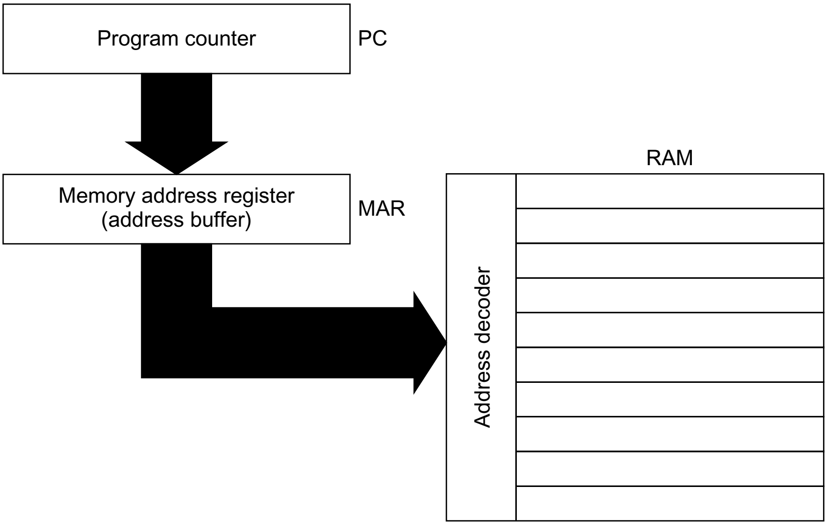

FIGURE 6.7 Program counter identifies the address in memory to be accessed.

condition. These flags can be monitored or tested by the control circuitry to change the sequence of processing.

The stack register is a 16-bit or larger register used to address a selected area of RAM known as the *stack*. This memory is used to store register contents and status information when subroutines and interrupts are used.

Instruction-Word Formats

There are three types of instruction formats used in typical 8-bit microprocessors, illustrated in Figure 6.8. In the single-word format, the instruction is a single 8-bit word. This word is called the *op code*. The op code tells the ALU, the registers, and other elements of the system what to do. In this format, no address is used. The focus of the instruction is implied in the instruction. That is, the data to be processed is already in a location designated by the instruction. Usually the data is in a register. Typical instructions using this format are register-to-register transfer, shift data left (or right), or clear to zero.

The two-word instruction format in Figure 6.8 requires two 8-bit words to define the operation. These two words are stored in sequential memory locations. The first word is the op code. The second word is usually an address that specifies a memory location where the data word to be processed is stored. For example, if the op code calls for an add operation, the address word designates the location in RAM of the number to be added to the contents of the accumulator. The 256 bytes of RAM can be addressed with 1 byte of address.

In some 2-byte instructions, the second byte is not the address. Instead, it is the data itself. This is called an immediate instruction since it is not necessary to address the data that is available immediately within the instruction itself.

FIGURE 6.8 Three common instruction-word formats with addresses or data.

The three-word instruction format in Figure 6.8 is comprised of an 8-bit op code and two 8-bit address words stored in sequential memory locations. The second and third bytes together form a 16-bit address word that designates the location in RAM of the data to be processed. In the 3-byte instruction format, the first byte is the op code, the second byte is the least significant half of the address, while the third byte is the most significant part of the address. Different formats are used by other micros.

To access a word in RAM, the instruction address word must be stored in the MAR. This happens during the instruction fetch operation. When an instruction is fetched from memory, the op code is stored in the instruction register while the address is stored in the MAR. The instruction is then executed. The MAR usually gets its input from the PC. Once an instruction is fetched and executed, the PC is incremented.

The PC may be incremented once, twice, or three times, depending on the length of the instruction just executed. If a 2-byte instruction is executed, the PC is incremented twice so that the PC points to the address of the next instruction op code.

Program Execution Example

Now let's illustrate how a typical CPU executes a simple program. Here are a few common instructions similar to those found in any micro.

Move A to B (MOV B,A): This is a 1-byte instruction that causes the content of the accumulator (A) to be moved to register B. The content of the accumulator is not erased.

Load Accumulator (LDA): This is a 3-byte instruction that takes the content of the address specified by the second and third bytes and loads it into the accumulator.

Add Immediate (ADI): This is a 2-byte instruction that takes the content of the second byte of the instruction and adds it to the content of the accumulator. The sum is stored in the accumulator, replacing the number that was there previously.

Halt (HLT): Halt is a 1-byte instruction that stops processing.

Note that we refer to each instruction by a three-letter abbreviation called a *mnemonic*.

Figure 6.9 shows a complete CPU and the RAM containing a simple program. The first instruction in the program is the LDA stored in location 0000.

To begin the execution, the address of the first instruction is loaded into the PC that points to the location of the instructions in RAM.

Next, the content of the PC is transferred to the MAR that addresses RAM. The LDA instruction op code is fetched and stored in the instruction register. The address bytes of the LDA instruction in locations 0001 and 0002 are then transferred to the memory address register. The address of the data to be loaded into the accumulator in bytes 2 and 3 is 0008. The desired data word in location 0008 is retrieved and loaded into the accumulator. This is the augend (23).

After the LDA instruction is executed, the number 23 is stored in the accumulator. Next, the PC is incremented three times. The ADI instruction is then fetched and stored in the instruction register. The number to be added is stored in location 0004.

This is an ADD immediate instruction where the second byte contains the data, in this case the addend (56). The number in location 0004H is 56, which is added to 23 in the accumulator, creating the sum 79. The mnemonic of the next instruction to be executed is MOV B,A in location 0005.

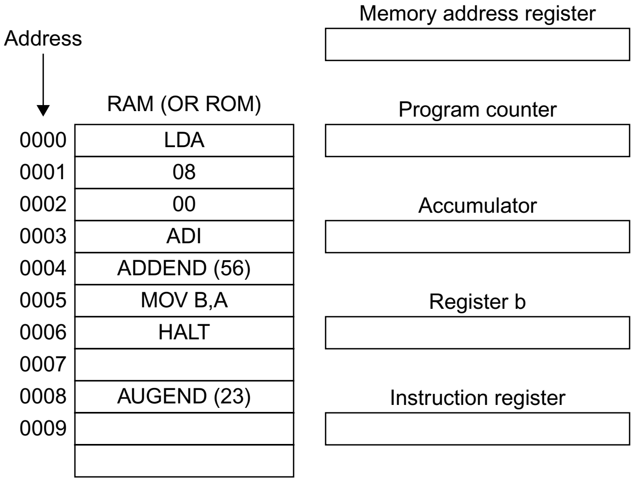

FIGURE 6.9 Example of program stored in RAM for execution using various CPU registers.

The sum in the accumulator is then moved to the B register by the MOV B,A instruction. The content of the accumulator is not changed when data is transferred to the B register.

The PC is incremented once since the HLT is a 1-byte instruction.

As you can see by this step-by-step analysis of the execution of a computer program, there is nothing mysterious about its operation. The CPU simply fetches and then executes the sequentially stored instructions at very high speed until the operation is complete. This process is sometimes referred to as the *stored program concept*.

Microcomputer Buses

Data transfers inside a microprocessor take place in parallel. This means that all bits in a word are transferred simultaneously from one place to another. It takes only a few nanoseconds (one billionth of a second) for all data bits in one register to be moved to another register.

The parallel data transfers take place over a data bus. A bus is simply multiple parallel electrical connections from a source to a destination. A number of these buses are contained within the CPU and are known as internal buses.

Microprocessors usually have three major buses—a *data bus*, an *address bus*, and a *control bus*. These are made available to external circuits in some micros. A typical 8-bit CPU has an 8-bit data bus and a 16-bit address bus. The data bus sends data to and from the CPU, RAM, ROM, and I/O sections. All data transfers between the CPU and memory or I/O sections take place over the data bus. The address bus drives all of the memory and I/O devices.

When an instruction is fetched from RAM or ROM, it is transferred over the data bus from the memory into the instruction register. Any data word retrieved from memory or a peripheral device via the input section also passes over the data bus into the accumulator or GPR.

When a store instruction is executed, the word in the accumulator is transmitted over the data bus into RAM. Data can also be transferred from the accumulator over the data bus to an external device such as an LCD. Or, data from an input device such as a keyboard passes over the data bus and is placed into the accumulator. The important point here is that data can move in either direction over the data bus. We say that it is a *bidirectional bus*.

Another key point is that the data bus can be connected to only one data source at a time. Data can originate only at a single source, but it can be sent to one or more destinations. To accomplish this, circuits called *bus multiplexers*, or *three-state line-driver circuits*, are used to connect or disconnect the various data sources to or from the bus. Figure 6.10 illustrates this concept.

The address bus is a unidirectional bus. It transfers an address from the CPU to all external circuits (memory and I/O). Address words are produced in the CPU. The PC generates the address that points to the instruction to be fetched. The content of the PC is transferred over a parallel 16-bit internal

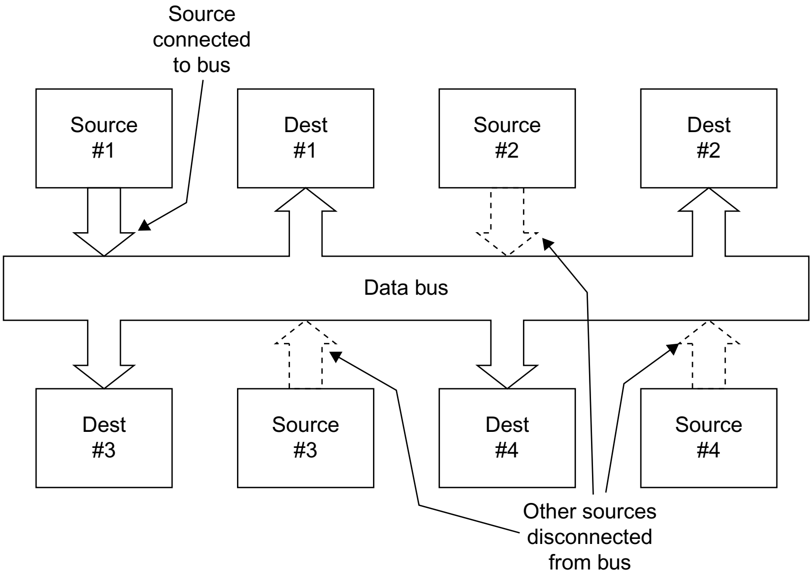

FIGURE 6.10 Only one source may transmit at a time on a bus. Others are disconnected. All destinations can receive the transmitted data. Dest=destination.

address bus to the memory address register or address buffer. The output of the MAR or address buffer is the address bus.

The control bus consists of numerous signals generated by the microprocessor and used to initiate various memory or I/O operations. The control bus also contains input lines from external circuits that tell the CPU what to do and when. The number of control signals varies from CPU to CPU.

POPULAR MICROS

The first practical microprocessors and microcomputers became available in the mid-1970s. Over the years lots of different models have been developed. As semiconductor processing technology has improved over the years, it has become easier and cheaper to put more circuits on a chip plus the memory that earlier was always external. And processing speeds have multiplied many times over. Today's embedded controllers are indeed complete computers on a chip and they run at very high clock rates. And their cost is low. In high-volume manufacturing, an embedded controller can cost less than $1.

Most of the initial processors were 8-bit devices. These are still popular today. Larger, faster processors are available for not much additional cost. Sixteen- and 32-bit processors are commonplace. Even 64-bit devices are available if needed. Many are individual chips, while others are available only as cores on a larger systems chip. Following is a summary of a few of the most widely used processors.

8- and 16-Bit Microcontrollers

8051

The 8051 is one of the oldest but still widely used. It was originally developed by Intel in the late 1970s and 1980s. It is still around and available from a half dozen or more companies. The more recent versions are faster and have more memory and I/O features than the original. Original clock speeds were only 8 to 12 MHz, but today you can get models with a clock rate up to 100 MHz.

A general block diagram of the 8051 is given in Figure 6.11. The 8051 features an internal RAM of 128 or 256 bytes but can handle 64 or 128 KB of RAM externally. The internal ROM can be had from 512 bytes to 128 KB. Some models also feature flash memory. As for I/O ports, the figure shows four 8-bit parallel I/O ports. You can get a standard serial port called a UART, and more specialized I/O ports such as SPI and I^2C. See the Interfaces sidebar in this chapter. Many models also come with an internal 10- or 12-bit ADC.

A few other items in this diagram that were not previously discussed are the clock, interrupts, and timers. The *clock* is an oscillator that controls all operations in the micro. Its frequency is usually set by an external crystal that maintains a precise and stable frequency. The higher the frequency, the faster the operations. Fast is good.

An *interrupt* is, as its name implies, an external signal that can interrupt the CPU when an important event occurs. It can signal the CPU of the event and even cause the CPU to stop executing the current program and jump off to another program to deal with the interrupt.

Timers are usually just one or more up/down counters than can be programmed with various count values. These are used to implement count functions in programs and to provide timing operations for I/O operations. Most controllers have one or more timers.

68HC11

Another widely used 8-bit controller is the Freescale 68HC11 and its various versions. There are dozens of offshoots and variations. It has two 8-bit accumulators and one 16-bit accumulator. Total memory space is 64 KB with 128, 256, or 512 bytes of RAM, and up to 48 KB of ROM program memory. Different versions have all the interfaces, both parallel and serial, and some models have a built-in 8-bit ADC. A 16-bit version called the 68HC12 is also part of the product mix.

PIC Processors

Microchip Technology makes one of the most widely used 8-bit controllers. Called PIC processors, they are extremely simple and cheap. There are hundreds of versions with different memory sizes and configurations and various mixes of interfaces. One of the simpler versions is the 16C54. It has a single

working register, W, that is the accumulator. It uses a bank of 24 to 73 registers for RAM. ROM for program storage ranges from 512 bytes to 2 KB. I/O occurs via 4- or 8-bit parallel ports. Larger versions have more RAM and more ROM, higher clock speeds, a built-in ADC, and special network interfaces like CAN. Several 16-bit versions are also available.

MPS430

A typical 16-bit microcontroller is the Texas Instruments MSP430. It has 16 GPRs and a clock speed of 16 MHz. On-chip RAM is SRAM, and can be had in versions with 128 bytes to 10 KB. ROM for the program is flash from 1 KB to 120 KB. It has an ADC on board, a DAC, timers, and all the common serial interfaces. It is a popular chip because its low power consumption makes it ideal for portable and battery-powered devices.

32- and 64-Bit Processors

As it turns out, it is almost as cheap and easy to make a 32-bit processor as it is to make an 8-bit device. For that reason, for a few cents more, designers can make their products faster and more powerful by selecting a 32-bit device. With this many bits being processed at the same time, it is possible to move more data faster, compute with increased resolution, and to perform much more complex operations faster and easier. Thirty-two-bit processors can also address much more memory. A few years ago, 32-bit processors were reserved for only the largest or most critical of needs. Today, the 32-bit processor is almost as widely used as the 8-bit processor.

Three devices account for most applications. They are made by ARM Holdings, Freescale, and MIPS. ARM is the name of a British company that invented a super-simple, fast, and flexible 32-bit processor that does everything well at very low cost. It is referred to as a reduced instruction set computer (RISC) processor. It has a few simple instructions but is extremely fast. ARM does not actually make chips, but instead licenses the design to others. There are several vendors of ARM processors but most of them are actually cores that are integrated on-chip with other circuits to form a system on a chip (SoC). With over 75% of the market share, you are sure to encounter an ARM device sooner or later. Chances are you own at least one inside a product such as a cell phone, which is where most are used.

Freescale's PowerPC is another popular 32-bit processor. It was originally used in Apple Macintosh computers but no more. IBM used it widely and still does in some products. Many embedded versions have since been made. Its primary usage is in communications, networking, automotive, and industrial applications.

For really super processing power, the MIPS processors are a popular choice for certain embedded applications. These devices come in 32-bit as well as 64-bit models, in case you really have a hot application for which nothing else will do. The MIPS processors are great at advanced math and have excellent resolution.

Microcontroller Interfaces

An *interface* is the circuitry that connects an embedded controller to the outside world. Initially, all I/O in early micros was just the parallel data and address buses extended to accommodate additional I/O circuitry. Today, much of the I/O interface circuits are put right on the same chip with the rest of the micro. Following are the most widely used interfaces you are likely to encounter. All of these are serial interfaces. Parallel I/O is still used, but today the preference is serial I/O because of fewer interconnecting lines.

RS-232/UART—This universal asynchronous receiver-transmitter is actually the physical circuitry implementing a popular serial interface standard referred to as RS-232. It was originally developed for connecting computers to teletype machines and early video terminals. It is still used today, especially for connecting to industrial equipment for monitoring or control.

The RS-232 interface sends and receives data in bytes (8 bits) plus two extra bits, called Start and Stop bits, that tell the receiving device when the data begins and ends (see Figure 6.12). The logic levels are −3 to −25 volts for a binary 1 and +3 to +25 volts for a binary 0. Typical voltage levels are in the 5- to 12-volt range. The data rate is slow, typically from 300 bps to 115.2 kbps. Standard data rates are used, so no clock signal is needed. Common speeds are 2400, 9600, and 19,200 bps. The physical communications medium is a two-wire (signal plus ground) cable that can be up to 50 feet long. Special 9- and 24-pin connectors are part of the standard. Many PCs and laptops still have a 9-pin RS-232 port.

I^{2}C—Shorthand for inter-integrated circuit or I squared C, this is a low-speed serial bus that is used for sending data from one chip to another on the same PC board or over short cables between two pieces of equipment. The data rate is typically in the 10 kbps to 400 kbps range, but a faster version (3.4 Mbps) is

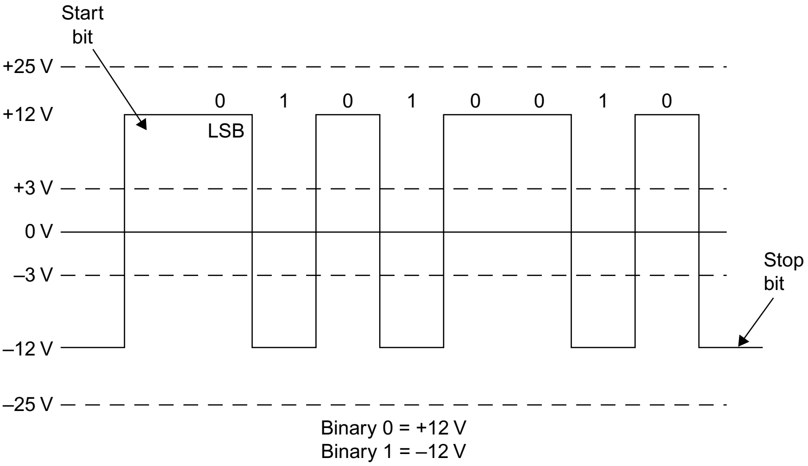

FIGURE 6.12 ASCII letter "j" being sent over an RS-232 interface using a UART.

(*Continued*)

Microcontroller Interfaces (Continued)

available. Speeds rarely exceed 100 kbps. Only three wires are needed, data, a clock signal that controls the data transfer, and a ground.

SPI—This is the serial peripheral interface. It uses four wires, data in, data out, clock, and a select signal that determines whether a device is a master or slave and either sending or receiving data. A fifth connection is ground. It is much faster than the I^2C interface, with speeds up to 20 Mbps.

CAN—This is controller area network serial bus in an interface used to link micros together in small networks. It is used in automotive and industrial applications. The usual cable is twisted pair and a ground. Speeds range from 10 kbps to 1 Mbps with 20 kbps being typical. The data is sent in specifically formatted frames as determined by a standard protocol. It uses start and stop bits like the RS-232 and some similar control codes defined in ASCII. It also includes error detection and correction capability, so it is very reliable.

USB—The universal serial bus is the most common PC interface for peripherals including keyboard, mouse, printer, flash drive, external disk, and so on. It is also used in some embedded micros. The interface uses two wires but also includes +5 volts DC and ground. Version 2.0 provides speeds to 480 Mbps over cables no longer than 16 feet. A new higher-speed version 3.0 is also available with speeds up to 5 Gbps. Data is sent in bytes in packets according to a unique protocol.

RS-485—This is an interface widely used in industrial applications. It uses twisted pair cable that can be up to 4000 feet long. The cable is actually a bus to which many devices can be attached. Data rates can be up to 10 Mbps for shorter lengths. Various protocols may be used.

A WORD ABOUT SOFTWARE

The microcontroller can perform almost any digital function from the simplest logic operation to a complex mathematical calculation. The only problem is that you have to tell it to do what you want. And you do that by programming. A program is the sequence of instructions that detail the order in which you do the various processing steps that lead to your application. The controller chip itself is a dumb piece of hardware waiting for its program. What this means is that today, designing an electronic product is as much about writing programs as it is building electronic hardware.

Software is the name given to all the programs that a processor uses for developing and executing a program. The program that implements your application is the applications program. Other types of software used with the processor follow:

Languages—A programming language is a set of rules or syntax that defines how you tell the processor what to do. A language is the tool that you actually use to create your application program. It is a kind of shorthand code that lets you express the operations in simple terms.

Editor—An editor is like a word processing program that lets you type in your program. You then save it as a file that the compiler or assembler uses to create machine code.

Compiler—A compiler is the program that translates your program code into binary code that can be stored in the memory and used by the processor. Processors only understand binary code but humans are not good with such code. So, you write your program in a language you can understand and the compiler converts it to the code that the processor understands.

Operating system—For large complex programs or for applications that require the processor to execute multiple programs at different times, you need a piece of software that manages the multiple programs and operations. The operating system (OS) oversees things like memory usage and access, timing, and I/O operations. Not all embedded controllers need an OS, just the more powerful ones with multiple functions. For example, most cell phones have an OS.

Development environment—This is a complete package of software tools that facilitates your software development. It consists of languages and compilers, as well as programs for testing and debugging your code.

Subroutines—These are short sections of code that perform a specific operation. It may be a math operation, some type of I/O process, or other function that is performed multiple times. You only write the subroutine once, and then access it when you need to do that operation. Many development systems have libraries of subroutines that you can tap so you do not have to program common functions yourself. Subroutines shorten your development time and speed execution.

Programming Languages

There are dozens of languages used from programming embedded controllers. The more popular ones are assembly language, C, and BASIC.

Assembly Language

Assembly language uses shorthand mnemonics such as three- or four-letter designations for the instructions that the processor can execute. Instead of programming with binary code, you use the mnemonics. In addition, you use names that you make up to identify memory locations, I/O ports, and other things normally referenced by a binary code. Following is what a simple assembly program looks like:

```
ORG $0000
LDAA FIRST
MUL SECOND
STA PRODUCT
OUT PORT 1
END
```

This programs loads one number from a memory location given the name FIRST, multiplies it by another number in memory location named SECOND. It then stores the result in another memory location called PRODUCT. It next outputs the value to an I/O port called PORT 1. The ORG $0000 simply says to start the program whose first instruction is in memory location 0000, a hex address.

The software that converts the assembly language program to binary code is the *assembler*. The assembler gives actual binary assignments to the memory locations named as well as the instruction op codes.

C Language

The C language is referred to as a higher-level language in that the various syntax and terminology of the language usually translates into multiple binary machine instructions. The C language lets you write the program in a more conversational or casual format using English instead of cryptic mnemonics and other terms. The language is a bit of a challenge to learn, but after that programming goes much faster. A compiler converts the C-language program code into binary code.

A simple C program may appear like this:

```
int x, y, z
x = 38
y = 57
z = 57 − 38
printf z
```

The first line identifies three integer values x, y, and z; 38 is assigned to x, and 57 to y. Then the difference between the two is designated z. Finally, the printf line accesses a subroutine that causes z to be printed.

BASIC Language

Some embedded controllers use a simplified version of BASIC. BASIC was invented before personal computers and initially became the main language of personal computer programming. Microsoft still sells its Visual BASIC software for program development. BASIC is very simple higher-level language that is easy to learn and use. The program created is then translated into binary code by a compiler. Alternately, the controller runs a program called an *interpreter* that resides in memory and executes the program a command at a time.

The following program is written in PBASIC, a simple version of BASIC used with an embedded controller called the BASIC Stamp made by Parallax. It uses a PIC microprocessor and stores a program in flash memory. The program causes an LED to flash off and on.

```
Flash
Output 7
High 7
Pause 500
Low 7
Pause 500
Goto Flash
```

The name of this program is Flash. The first line tells the controller to make pin 7 the output port. The next line tells pin 7 to go high or to binary 1. The next command says pause for 500 milliseconds. Next, pin 7 is made to go low or to binary 0 via the Low command. Pause makes it stay there for another 500 milliseconds. Finally, the Goto command causes the program to look back and repeat itself again and again. The result is an LED that turns off and on at a 1000-millisecond (1-second) rate.

DIGITAL SIGNAL PROCESSING

Digital signal processing (DSP) is the technique of programming a microcomputer to perform operations normally carried out by analog or linear circuits. The method is illustrated in Figure 6.13. Assume you want to process an analog signal by filtering. You could use a hardware filter made up of inductors and capacitors or resistors and capacitors. Another way to do it is with DSP. The analog signal to be filtered is first digitized with an ADC and the resulting data stored in a RAM. This data is then acted upon by a processor programmed to perform a filter function. Special mathematical algorithms have been developed to do this. The resulting calculations generate new data that is also stored in the RAM. This new data is then sent to a DAC where it is converted back to an analog signal. The result is that the signal is filtered as if were processed by an electronic circuit of capacitors and inductors. The processing was mathematical.

There are many other operations that can be performed by DSP. Filtering is the main application, but you can also do things like modulation and demodulation as needed in wireless applications. It will perform other things such as data compression, equalization, tone control, and even frequency analysis.

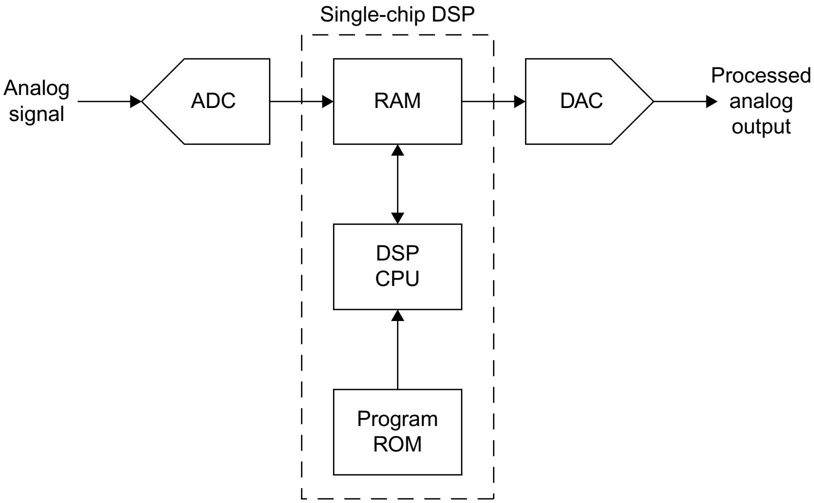

FIGURE 6.13 Basic make-up of digital signal processor and its ADC and DAC I/O.

Using a program called the fast Fourier transform (FFT), the DSP can analyze a signal and tell you exactly what frequency components are in it. It identifies the harmonic frequencies and their various amplitudes and phases just as in a frequency-domain plot.

The big question is why use a complicated technique such as DSP when you can do it with simple analog/linear hardware? Probably the best answer is "just because we can." With cheap single-chip processors, DSP is often no more expensive than an equivalent analog circuit. Since everything else is digital these days, it makes some sense to do as many analog functions digitally as well. But the best reason is that DSP provides superior results over analog methods. Filtering is substantially improved with better selectivity that was not possible with analog filters.

While DSP can be programmed on any processor or controller, it is best done on special DSP chips designed for the purpose. They use special architectures and processing schemes to speed up and improve the processing over standard conventional processors. A good example is that DSP chips implement a multiply and add or accumulate function, called MAC, that is common to most DSP processes. The MAC has to be programmed in a standard processor, but in a DSP chip it is implemented with special hardware that speeds up the process and simplifies programming. Some more conventional processors also incorporate DSP instructions to facilitate DSP operations.

Now that DSP chips are cheap despite their complexity and speed, DSP is widely used. It is found in most electronic products today, such as TV sets, cell phones, MP3 players, cable modems, and many other common products.

Project 6.1

Use a Microcontroller

One of the fastest ways to get familiar with a microcontroller is to use the BASIC Stamp made by Parallax. It comes as a complete unit with a microchip technology PIC processor and I/O circuits. One is a USB port to a personal computer. The software provided lets you program the controller in PBASIC. You write the program on a personal computer and download it to the EEPROM in the PIC. Then you run the program. It is ideal as a way to monitor and control lots of simple devices. And it is a fast and easy way to see firsthand what a controller does.

Go to the Parallax website at www.parallax.com and find the BASIC Stamp info and just order one. There are various models, from the ultra simple to the complex, and lots of accessories to help you implement various applications.

Radio/Wireless

The Invisible Cables of Modern Electronics

In this Chapter:

- The oldest electronic application.
- What are radio waves?
- The electromagnetic frequency spectrum.
- The hardware of radio: transmitters, receivers, and antennas.
- Two-way radio applications.
- Satellites.
- Radio telescopes.

INTRODUCTION

First they called it wireless. Then they called it radio. Today, the term *wireless* is trendy again. Whatever you call it, radio is communication over a distance without any physical connection. Radio is cool because it is completely silent and invisible. It can occur over a distance of only a few feet, all the way around the world, or between planets and spacecraft. Radio, despite the fact that it has been around for over a century, and the fact that we take it for granted on a grand scale, is truly black magic. When you finish reading this chapter, you will know how this magic works.

RADIO COMMUNICATION SYSTEMS

Radio is an electronic communications system. All electronic communications systems have the basic form shown in Figure 7.1, whether it is a wired or wireless system. The information to be communicated, usually voice, is first converted into an electrical signal by a microphone. That signal is then processed by the circuits in a transmitter (TX), and then sent via a communications medium to a receiver (RX) that processes the signal and converts it back into voice by a speaker or headphones. In the telephone system, the communications medium is a cable made of copper wire. In a cable TV system, the medium is a coaxial cable, twisted-pair cable, or fiber optic cable. But in radio, the communications channel is free space. The radio signal travels from one place to another almost instantaneously and it passes right through

most obstructions like walls, buildings, smog, trees, and even people. Note that noise is added to the signal as it passes through the channel or medium.

Noise

Noise is any random electrical voltage that interferes with the weak radio signal. Noise comes from the atmosphere, space, human-made objects, and electronic components. Atmospheric noise is lightning. Space noise comprises random signals from the Sun and remote stars. Human-made noise comes from electrical power generation, distribution, and switching. It also comes from fluorescent lights, motors, auto ignitions, and many other sources. The worst noise comes from the electronic components that actually process the weak radio signal. Resistors, transistors, and integrated circuits generate random noise because of thermal agitation. Heat produces random movement of the electrons in the components, and that produces a noise voltage which is added to the radio signal. Even though noise voltages are very small (microvolts or nanovolts), they are still large enough to interfere with and in some cases obliterate the very small received radio signal. In most radio systems, it is noise that limits intelligibility, transmitted data speed, and transmitted distances.

THREE BASIC WAYS OF COMMUNICATIONS

Radio communications systems work in one of three basic ways, simplex, half duplex, and full duplex (see Figure 7.2).

FIGURE 7.2 Ways of communicating.

Simplex

Simplex is one-way communications. Examples are radio broadcasting, paging, and remote control. A radio telescope is also one-way: there is a transmitter at one end and a receiver at the other.

Half Duplex

Duplex means two-way, and most radio communications are really two-way affairs. There is a transmitter and a receiver at both ends of the communications system. Both parties can send and receive. And there are two types of duplex systems, half duplex and full duplex.

In half-duplex systems, only one party can transmit at a time. Those communicating with one another take turns talking. This is the kind of radio where you have to say "over" or "come back" after you finish speaking to let the other party know that it is time for her or him to talk. CB radio is like this. Most two-way communications services (police, fire, taxi, aircraft, marine, etc.) use this method because it is cheap and simple. Fax machines are half duplex. Most computer modems are half duplex.

Full Duplex

Full duplex is more complex and expensive. This is two-way radio where both parties can both send and receive simultaneously. Probably the best example of this is a cordless or cellular telephone. It is great to be able to talk and listen at the same time.

WHAT IS A RADIO WAVE ANYWAY?

Any discussion of radio always gets around to this basic question. How do you describe something that you cannot see, feel, or hear? You imagine it.

Electric and Magnetic Fields

A radio wave is an invisible force field that is made up of both a magnetic field and an electric field. In combination, we call them an *electromagnetic field*. We can't see or feel them, but we can experience their effects. In Chapter 2, electric and magnetic fields are described briefly. To review, a magnetic field is a force generated by a magnet, either a permanent magnet or electromagnet. Current flow in a wire or other conductor produces the magnetic field. Invisible magnetic flux lines emanate from the magnet and may influence objects in or near them.

An electric field derives from a voltage, or what we call a *potential*, across two conductors. The attraction of the positive and negative charges across an open space introduces another kind of invisible field that can also influence external objects.

Now if you combine these two types of fields into a self-supporting entity, you would have an electromagnetic field or *radio wave*. We create a radio signal with the circuits in a transmitter, but it is the magic of a device called an *antenna* that produces the combined electric and magnetic field that we refer to as a radio wave.

In the 19th century, a British scientist named James Clerk Maxwell figured out that if you generate a changing electric field, it would, in turn, generate a magnetic field. If the magnetic field is changing and moving forward, it will generate an electric field. The two fields support or regenerate one another as they change and move outward from the antenna that produces them. Maxwell expressed his theories in his famous mathematical equations that form the foundation of radio and light transmission.

Trying to draw a picture of a radio wave is somewhat like trying to draw a picture of the wind. Nevertheless, Figure 7.3A is an attempt. Try to think in three dimensions. Current flow in the antenna wire creates the magnetic field lines. The voltage across the two segments of the antenna produces the electric field lines. The picture is somewhat simplified if we just show the field lines as in Figure 7.3B. The electric and magnetic field lines are always at right angles (90 degrees) to one another. The radio wave moves in a direction at a right angle to both field lines, in this case either into or out of the page. As it gets some distance from the antenna, it becomes self-supporting. That is, the magnetic field sustains the generation of the electric field and vice versa.

Polarization

Polarization of a radio wave means how it is oriented with respect to the surface of the Earth. If the electric field is vertical to the surface of the Earth, the wave is vertically polarized. If the electric field is horizontal to the Earth, the wave is horizontally polarized. It is the orientation of the antenna generating the radio signal that determines the polarization. A vertical antenna produces vertical polarization, and a horizontal antenna produces horizontal polarization. For the best reception, the transmitting and receiving antennas should both be either vertical or horizontal.

There is also circular polarization. Some antennas make the signal rotate clockwise or counterclockwise as the signal travels from transmitter to receiver. Clockwise rotation, as viewed from the transmitter, is called right-hand circular polarization (RHCP). Counterclockwise rotation is called left-hand circular polarization (LHCP).

Signal Speed

Radio waves travel at the speed of light in space. That is 300,000,000 meters per second or 186,410 miles per second. So while radio transmission is not

instantaneous, it is pretty fast. Just as an example, to transmit a signal to the moon that is 250,000 miles away takes 250,000/186,400 = 1.34 seconds.

Signal Strength

As the radio wave gets farther and farther from the antenna, it gets weaker and weaker. The power in a radio wave, in fact, decreases by the square of the distance from the antenna. For example, doubling the distance decreases the received power by two squared (2^2) or four. Even when the transmitter puts many hundreds or thousands of watts of power into the antenna, the signal received at a distance is many times smaller. Typical radio signals are usually expressed in terms of microwatts (1-millionth of a watt) or nanowatts (1-billionth of a watt).

As the radio wave encounters a receiving antenna, the magnetic and electric fields induce a voltage into the antenna. This tiny voltage is then amplified and translated back into the original information signal by the receiver.

ELECTROMAGNETIC FREQUENCY SPECTRUM

The radio signal applied to the antenna by the transmitter is a sine wave. Remember that all sine waves have both an amplitude and a frequency. Frequency is stated in terms of cycles per second or hertz (Hz). Radio transmissions can take place over a very wide frequency range. We call this range the *electromagnetic frequency spectrum*. It extends from approximately 10 kHz to 300 MHz. Figure 7.4 shows a diagram designating the major divisions of the electromagnetic spectrum.

The electromagnetic spectrum is in free space, not only here on Earth but throughout the universe. The spectrum space may be used by anyone and, in fact, on Earth we all share it. The spectrum is divided up and used for many different radio services. It is also partitioned such that various frequency ranges are assigned to or used by different countries for their various radio services. In many cases, portions of the frequency spectrum are shared concurrently among several countries. This allocation of the frequency spectrum is necessary to prevent radio stations from interfering with one another.

In the United States, the frequency spectrum is regulated by the Federal Communications Commission (FCC). Congress established the Communications Act of 1934, which has subsequently been amended to permit the FCC to regulate all forms of radio and wired (telephone, cable TV, etc.) communications services. The National Telecommunications Information Administration (NTIA) manages the spectrum for the government and the military. Throughout the world, the frequency spectrum is allocated and managed by a worldwide organization known as the International Telecommunications Union (ITU).

Major Segments of the Frequency Spectrum

30 kHz to 300 kHz—Low frequencies (LF)
300 kHz to 3 MHz—Medium frequencies (MF)
3 MHz to 30 MHz—High frequencies (HF) or shortwaves
30 MHz to 300 MHz—Very-high frequencies (VHF)
300 MHz to 3 GHz—Ultra-high frequencies (UHF)
3 GHz to 30 GHz—Super-high frequencies (SHF)
30 GHz to 300 GHz—Extremely high frequencies (EHF)

The various areas of the frequency spectrum are assigned to different types of communications services. For example, in the low-frequency (LF) range, most communications services are navigational systems used by the Coast Guard and military. The AM broadcast band (530 kHz to 1710 kHz) is in the

medium-frequency (MF) range. Shortwave (SW) radio broadcasts, CB radio, amateur radio, and a variety of other communications services are in the 3 to 30 MHz or high-frequency (HF) range.

One of the most widely used areas of the spectrum is the VHF range from 30 to 300 MHz. Virtually all two-way radio communications for marine, aircraft, mobile, and other services are in this range. FM broadcasting (88 to 108 MHz) and TV channels 2 through 7 are also in this region.

The UHF frequency range, from 300 MHz to 3000 MHz (3 GHz), also contains a wide variety of communications services. It includes two-way mobile radio, TV, and cellular telephone.

Frequencies above 1 GHz are designated as microwaves. In the microwave region between 1 and 3 GHz are satellite and navigational systems. For example, the widely used global positioning system (GPS) operates in this range. This area is also occupied by the newer cellular telephone service and wireless networks such as Wi-Fi and Bluetooth.

The frequencies from 30 GHz to 300 GHz are called millimeter waves because their wavelength is in millimeters. These frequencies are typically used only by satellite and radar systems. Other services are point-to-point wireless data services and cellular backhaul. Some short-range wireless devices have also been defined for the 60-GHz range. These will be used in consumer applications as well as in faster wireless networks.

Critical Issue: Spectrum Space

There is only so much radio spectrum space and we must all share it. It is a true natural resource. That's why spectrum space is regulated by governments. But we have just about used it all up. Virtually every hertz of space is spoken for. Diverse radio services compete for space. In some cases, an old service must die before a new one can begin. Sometimes space is stolen from one service to give to another, such as in the mid-1980s when the upper UHF TV channels were sacrificed to make room for cellular telephones. Lately, the U.S. government has been selling space to the highest bidders for new cell phone and other wireless services. During the recent switchover to digital TV in the United States, a huge chunk of the spectrum was freed up (108 MHz, from 698 to 806 MHz) as TV stations abandoned this region. Known as the 700-MHz band, it was auctioned off by the government for $19.6 billion for more cell phone spectrum as well as broadband wireless services and cell phone TV.

The trend has been to push higher and higher in the frequency range to find more space. During the past several decades, the microwave region (above 1 GHz) has been developed. This region, in the UHF, SHF, and EHF ranges, was previously used only for radar and satellites. But now it is being used and developed for digital cell phones, navigation, high-speed networking, broadband (Internet) wireless, and digital TV.

Beyond the millimeter wave range above 300 MHz is the optical spectrum. That is, above 400 GHz, the electromagnetic radiation becomes light, namely infrared, visible light, and ultraviolet light. But that's another story altogether.

Wavelength

While we normally use frequency to refer to location of a radio signal in the spectrum, sometimes you will hear about frequencies or ranges of frequencies designated by wavelength.

Wavelength is the actual physical length of a radio wave. It is the amount of space the wave occupies. Specifically, wavelength is the length of one cycle of the sinusoidal variation of the electromagnetic fields. If we could see the electric and magnetic fields, we could measure the distance between the maximum intensity points in meters (1 meter = 3.28 feet or 39.37 inches). This is the wavelength. Wavelength is also the distance that the radio wave travels in the time of one cycle.

You can determine the wavelength of a radio signal with the following simple formula:

$$\lambda = 300{,}000{,}000/f$$

Wavelength is represented by the Greek letter lambda (λ) and frequency in hertz is designated by the letter "f." The value 300,000,000 is the speed of light of a radio wave in meters per second in free space. (This translates to a speed of 186,410 miles per second.)

A radio signal with a frequency of 150 MHz is expressed in hertz as 150,000,000 Hz. Therefore,

$$\lambda = 300{,}000{,}000/150{,}000{,}000 = 2 \text{ meters}$$

If we give the frequency in megahertz, the formula can be shortened to:

$$\lambda = 300/f$$

For example, we can calculate the wavelength of the shortwave or high-frequency part of the spectrum (3 to 30 MHz) as follows:

$$\lambda = 300/3 = 100 \text{ meters}$$
$$\lambda = 300/30 = 10 \text{ meters}$$

If you rearrange the formula, you can also find the frequency if you know the wavelength:

$$f = 300/\lambda$$

What is the frequency of the 25-meter band?

$$f = 300/25 = 12 \text{ MHz}$$

RADIO WAVE PROPAGATION

Propagation refers to the way in which a radio signal travels from the transmitting antenna to the receiving antenna. The way the signal behaves is directly related to its frequency.

Low and Medium Frequencies

For example, in the low-frequency and medium-frequency ranges, the radio signals tend to hug the Earth as they move from transmitter to receiver. These ground wave signals can only travel relatively short distances because they are absorbed and attenuated by the Earth, trees, buildings, and other obstructions. Depending on the frequency of operation, transmitter power, and the nature of the terrain, distances are limited to several hundred miles. Distances can be extended with greater power or if the signal travels over water.

High Frequencies

In the HF or shortwave frequency range, the ground waves are extremely weak and travel only short distances, usually several miles. Instead, propagation is by way of refraction of the ionosphere. The ionosphere is an electrified area above the Earth located from approximately 30 miles to 250 miles above the Earth. The Sun ionizes the gases in the air, thereby giving them electrical characteristics. The closer the ionosphere to the Sun, the greater the degree the ionization. The ionosphere is actually several different layers or ionization levels as shown in Figure 7.5. The upper layers have greater ionization than the lower layers. Obviously, the degree of ionization is determined by whether it is day or night. During the daylight hours, the ionosphere is highly charged electrically. At night, the ion layers essentially disappear.

A radio wave in the 3- to 30-MHz range is transmitted up to the ionosphere where it is refracted or bent by ionization. The degree of bending depends on the frequency of operation and how high in the ionosphere the radio wave penetrates. In most cases, the radio wave is bent so much that it actually returns to Earth. The effect appears to be similar to that of a light beam being reflected from a mirror.

FIGURE 7.5 Radio propagation of shortwaves.

As you can see, the radio wave actually returns to the Earth at some distance from the transmitter. Receiving stations in the area of the refracted signal can receive it. In some cases, if the signal is strong enough and the characteristics of the Earth are right, the radio signal may actually be reflected by the Earth back up to the ionosphere where it is again bent and returned to Earth. Under the right conditions, the radio signals can make several hops, thereby greatly extending the distance of communications. With the optimum frequency, power level, and time of day, communications halfway around the world can easily be achieved. That is why it is easy for you to listen to worldwide radio broadcasts that occur in the shortwave frequency bands.

VHF, UHF, and Microwaves

Radio wave propagation in the frequency range above 30 MHz occurs essentially by direct antenna-to-antenna space waves. This is usually called *line-of-sight (LOS) communications*. Further, the higher the frequency of the radio wave, the less it is affected by the ionosphere. UHF and microwave signals penetrate the ionosphere, making satellite and long-distance spacecraft communication possible.

LOS communications means that the transmitting antenna must be able to "see" the receiving antenna. If the distance of the receiving antenna is beyond the curvature of the Earth, the transmitted signal will simply pass over the antenna. To receive the signal, the receiving antenna or transmitting antenna can be increased in height, thereby extending the total range of communications. Figure 7.6 shows this idea. The simple formula along with it allows you to calculate the maximum LOS communications if you know the height of the receiving and transmitting antennas. That's why at VHF, UHF, and microwave

$$D = \sqrt{2H_t} + \sqrt{2H_r}$$

$D =$ Line-of-sight distance (miles)
$H_t =$ Height of transmitting antenna
$H_r =$ Height of receiving antenna

If $H_t = 200$ ft and $H_r = 40$ ft,

$$D = \sqrt{2(200)} + \sqrt{2(40)} = \sqrt{400} + \sqrt{80}$$

$$D = 20 + 8.94 = 28.94 \text{ miles}$$

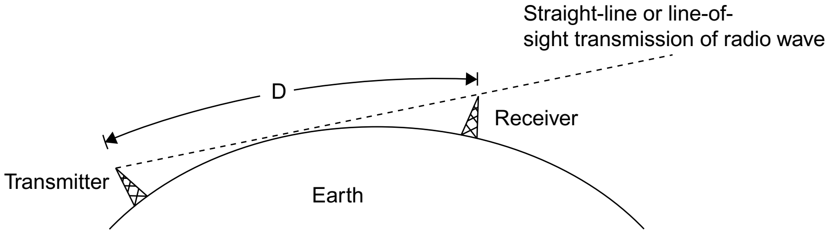

FIGURE 7.6 Line-of-sight (LOS) communications at VHF, UHF, and microwave.

frequencies, the height of the antenna is the most critical determining factor in overall communications distance.

MODULATION

A radio wave is a sine wave of voltage that has been converted into electric and magnetic fields by the antenna. The transmitter generates the sine wave and amplifies it to a high power level. The question is, how does the information to be transmitted fit into this?

The information or intelligence to be conveyed is usually a voice signal produced by a microphone. Other forms of intelligence signals include pictures or video and digital (binary) data from a computer. The purpose of the high-frequency sine wave radio signal is to give the intelligence signal a ride. That's why the radio signal generated by the transmitter is called the carrier. Modulation is the process by which the information is impressed on or embedded in the carrier. Modulation causes the carrier to be modified by the information signal.

There are three basic forms of modulation used to put information on a carrier: *amplitude modulation* (AM), *frequency modulation* (FM), and *phase modulation* (PM).

Amplitude Modulation

In amplitude modulation, the voltage or power level of the information signal changes the amplitude of the carrier in proportion (see Figure 7.7). With no modulation, the AM carrier is transmitted by itself. When the modulating information signal (a sine wave) is applied, the carrier amplitude rises and falls in accordance. The carrier frequency remains constant during amplitude modulation.

Amplitude modulation is widely used in radio. AM broadcast stations are, of course, amplitude modulated. So are citizens band radios, aircraft radios, and the video modulation of a TV broadcast transmitter. A special form of amplitude modulation, known as quadrature modulation (QAM), is also widely used in modems to transmit digital data over cable or wireless.

Sidebands

The modulation process causes new signals to be generated. These new sine wave signals are called sidebands. Their frequencies are the sum and difference of the carrier and modulating signal frequencies. For example, in an AM radio station, audio frequencies as high as 5 kHz can be transmitted. If a 5-kHz sine wave tone is to be transmitted, the modulation process causes sidebands 5 kHz below and 5 kHz above the carrier to be produced. This is illustrated in Figure 7.8. For an AM radio station with a carrier frequency of 860 kHz, the

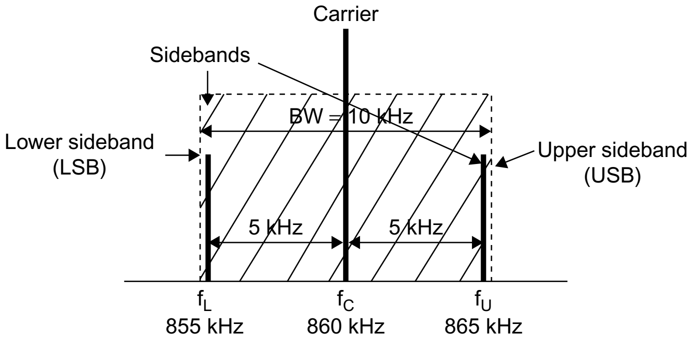
lower sideband (LSB) would occur at 860 − 5 = 855 kHz, while the upper sideband (USB) occurs at 860 + 5 = 865 kHz. The carrier and the sidebands combined produce the composite waveform shown at the bottom of Figure 7.7.

Bandwidth

This brings up the very important concept of bandwidth. Bandwidth refers to a range of frequencies over which a radio signal operates. This is also referred to as a radio channel. As you can see from Figure 7.8, the AM signal consists of the carrier and the sidebands. Together these signals occupy a bandwidth of 10 kHz. You can figure out the bandwidth of any signal by simply subtracting the lower sideband frequency from the upper sideband frequency.

$$\text{BW} = \text{USB} - \text{LSB} = 865 - 855 = 10\ \text{kHz}$$

All of the receiver circuits must be set to pass signals in this 10-kHz range in order to avoid distortion of the signal or lost information.



f_M = Frequency of modulating signal (5 kHz)
f_C = Carrier frequency (860 kHz)
f_L = Lower sideband frequency
f_U = Upper sideband frequency

$$f_L = f_C - f_M = 860 - 5 = 855 \text{ kHz}$$
$$f_U = f_C + f_M = 860 + 5 = 865 \text{ kHz}$$

$$BW = f_U - f_L = 865 - 855 = 10 \text{ kHz}$$

FIGURE 7.8 Sidebands and bandwidth.

Frequency Modulation

In frequency modulation, the carrier amplitude remains constant but its frequency is changed in accordance with the modulating signal. Specifically, the higher the amplitude of the information signal, the greater the frequency change. The actual carrier frequency deviates above and below the center carrier frequency as the information signal amplitude varies. Figure 7.9 shows frequency modulation with a sine wave information signal. Note that the carrier frequency gets higher on the positive peaks and lower on the negative peaks of the information signal.

Like AM, FM also produces sidebands. But unlike AM, which produces a single pair of sidebands for each frequency in the modulating signal, the frequency-modulation process produces an infinite number of pairs of sidebands for each frequency in the information signal. As a result, the bandwidth occupied by an FM signal is enormous. Luckily, the number of sidebands produced can be controlled by properly selecting the amount of deviation permitted in the carrier. Small deviations result in fewer sidebands. Further, some of the higher-order sidebands are extremely low in amplitude and, therefore, contribute little to the FM signal. But while the bandwidth of an FM signal can be controlled and established to fit a desired frequency range, it does nevertheless usually take more room in the spectrum than an AM signal.

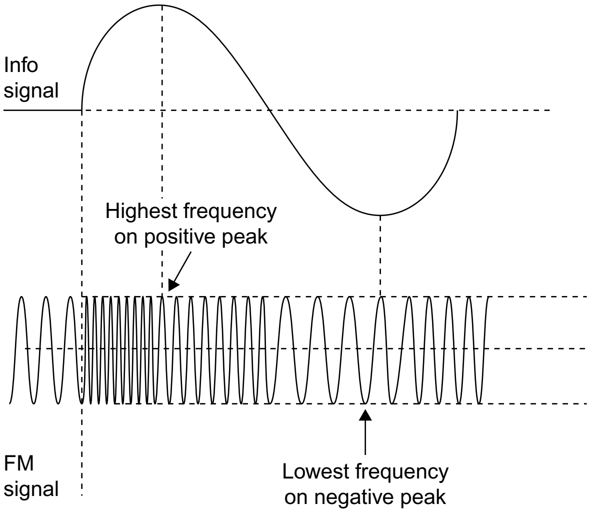


FIGURE 7.9 Frequency modulation.

The primary benefit of FM is that it is less sensitive to noise, which consists of undesirable amplitude variations that get involuntarily added to a signal. Noise is easily eliminated in an FM system where a constant carrier amplitude is used. Some of the most common applications of FM include FM radio broadcasting, and two-way mobile and marine radios.

Phase Modulation

The third type of modulation is phase modulation. Remember that phase shift is a time shift between two sine waves of the same frequency. We can use the information signal to shift the phase of the carrier with respect to the carrier reference. The result of this, however, is a signal that looks virtually the same as an FM signal (Figure 7.9). Phase modulation is usually a little easier to implement electronically than FM, so most so-called FM systems typically use phase modulation instead. Both FM and PM are often referred as types of *angle modulation*.

Digital Modulation

All of the three basic types of modulation, AM, FM, and PM, can also be used to transmit digital or binary data. However, they are usually given different names. Amplitude modulation of a carrier by a binary signal is usually referred to as amplitude shift keying (ASK). This is illustrated in Figure 7.10A. The binary signal simply shifts the carrier amplitude between two specific levels. A special form of ASK is called on–off keying (OOK). This is illustrated in Figure 7.10B. Here the binary signal simply turns the carrier on for a binary 1 and off for a binary 0.

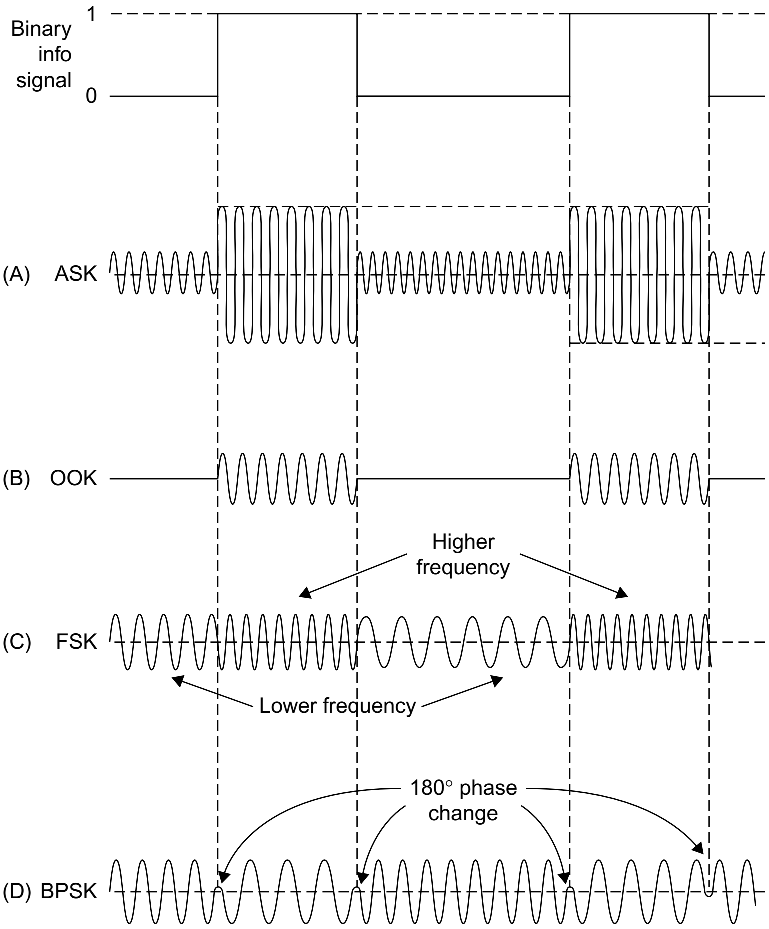

FIGURE 7.10 Types of digital modulation. **(A)** ASK. **(B)** OOK. **(C)** FSK. **(D)** BPSK.

Frequency modulation of a carrier by a binary signal is called frequency shift keying (FSK). Here the binary signal shifts the carrier between two discrete frequencies (see Figure 7.10C).

Phase modulation of a carrier by a binary signal is referred to as phase shift keying (PSK). The term binary PSK (BPSK) is also used. The phase of the carrier is changed as the binary signal switches from 0 to 1 or 1 to 0 (see Figure 7.10D). Phase shift is 180 degrees, which is easily detected at the receiver.

One of the most widely used forms of digital modulation is QAM, which is really a composite of both AM and PSK. The binary signal is converted into a multilevel digital signal that simultaneously modifies both the amplitude and the phase of the signal. QAM is used in digital data transmission in satellites and in modems sending digital data in audio form over telephone lines or cable

TV systems. It is also widely used in the newer digital wireless networks. See Chapter 8 for more detail.

Because binary signals contain many higher-frequency harmonics, the resulting signals produced by modulation have an enormous bandwidth. Many schemes have been developed to limit the spectrum of the modulating signal and, as a result, to reduce the amount of bandwidth occupied by a binary modulated radio signal.

Spread Spectrum

Spread spectrum (SS) is unusual in that it is not only a form of modulation but also a system for encrypting the information signal for security purposes and for multiplexing multiple signals over a range of frequencies.

Spread spectrum was originally developed during World War II as a way to prevent the enemy from interpreting radio transmissions. For years the government and military protected the concepts of SS modulation. However, today it is widely used in radio and telephone communications. Most of the newer cellular telephones are based on this concept, specifically code division multiple access (CDMA) cell phones.

When using SS, the analog information signal is converted into a digital signal before transmission. The digital voice signal is then used to modify the carrier in a special way. The two most common ways of modifying the carrier are referred to as *direct-sequence* (DS) and *frequency-hopping* (FH) *spread spectrum*. In direct-sequence SS, the serial digital signal representing the voice is chopped up into random sequences and then used to PSK the carrier. In frequency-hopping SS, the carrier is rapidly switched from one frequency to another for a short dwell time. The result of SS modulation is that the signal itself is broken up at random, and spectral energy is spread over a very wide frequency range. Because of the random sequences of the coding and frequency hopping, such a radio signal is nearly impossible to put back together at a receiver without knowing the code. SS receivers designed to pick up the SS signal know the code, and can unscramble the signal and reassemble it into the original modulating information signal.

RADIO HARDWARE

All radio communications systems consist of three basic pieces of hardware: *transmitter*, *receiver*, and *antenna*. In some systems, the transmitter and receiver are packaged and used separately, while in others they are combined into a single package and called a *transceiver*.

Transmitters

The radio signal is produced by the transmitter. A general block diagram that applies to virtually every transmitter is shown in Figure 7.11. The radio signal

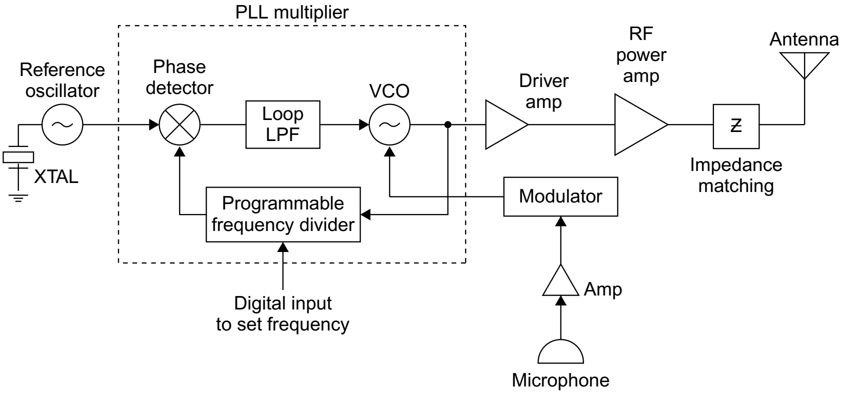

FIGURE 7.11 Radio transmitter.

is generated at a low power level by a frequency synthesizer. This uses a phase-locked loop (PLL) with a crystal (XTAL) oscillator reference. A variable-frequency divider is used to set the frequency of operation. The FCC is really fussy about the frequency at which transmitters work and, therefore, the frequency must be precisely set and extremely stable. A quartz crystal reference oscillator is normally used to achieve this objective.

The low-level signal produced by the voltage-controlled oscillator (VCO) is then amplified by one or more driver amplifiers to boost the power level. Next, the microphone signal is fed to the modulator. The modulator changes the frequency or phase of the RF signal in accordance with the voice, digital data, or other information to be transmitted. That signal is applied to the PLL VCO.

The modulated signal is sent to additional RF power amplifiers, usually referred to as *drivers*. Each succeeding stage boosts the signal power by a specific amount. A final RF power amplifier produces the desired amount of output power. From there, impedance (Z) matching circuits are used to match the high-power amplifier to the antenna for maximum power radiation.

The physical realization of the transmitter can vary all the way from a single integrated circuit chip the size of a postage stamp to something that can fill up a moderately large building. The size depends on the operating frequency and the amount of output power desired. Very-low-power, high-frequency radio transmitters for garage door openers and remote keyless entry systems on cars are fully self-contained within a single integrated circuit. High-power radio broadcast transmitters at low frequencies may fill a small room. The higher the power and the lower the frequency, the larger the transmitter.

Receivers

The job of the receiver is to translate the weak radio signal picked up by the antenna into an output that fully recovers the originally transmitted information.

By the time the radio signal reaches the receiving antenna, it is extremely weak and, therefore, the primary job of the receiver is to boost the signal level. Therefore, the receiver consists mainly of a series of amplifiers that increase the level of the small signal to a point where the original information can be recovered.

The amount of amplification provided by a receiver determines its *sensitivity*. Another job of the receiver is to provide selectivity so that the desired signal can be picked out of the thousands of signals being transmitted simultaneously by other transmitters. The receiver's job is to select just the desired one and to reject all of the others. This is what we refer to as the *selectivity* of the receiver.

A third function of the receiver is to recover the original information. A circuit called a *demodulator* removes the voice, video, or digital data from the carrier. Finally, output amplifiers reproduce the signal as desired, such as a voice signal in a speaker.

Figure 7.12 is a block diagram of a superheterodyne receiver. The incoming signal is usually amplified by an *RF input amplifier* often called a *low-noise amplifier* (LNA) and then fed to a circuit called a *mixer*. The mixer is a frequency-translation circuit that converts the incoming signal, regardless of its frequency, along with its modulation to a lower intermediate frequency (IF). This allows the receiver to use a fixed-frequency amplifier system where most of the gain and selectivity of the receiver is achieved. The mixer takes the input signal and mixes it with a high-frequency sine wave signal generated internally in the receiver by what is called a local oscillator (LO). The LO is usually a frequency synthesizer. The result of the mixing is output signals that are the sum and difference frequencies of the input and oscillator signals. The IF amplifier is normally tuned to select only the difference frequency. Tuning is accomplished by changing the local oscillator frequency. The local oscillator in most channelized receivers is some type of PLL frequency synthesizer.

The IF amplifier boosts the signal level considerably. Its selectivity ensures that signals whose frequencies are above or below the desired signal are effectively eliminated. The IF amplifier also has a built-in feedback control circuit that automatically adjusts its gain to the level of the incoming signal. This feature is called *automatic gain control* (AGC). AGC permits the receiver to pick up both strong local signals and very weak distant signals. When very strong signals are received, the AGC automatically reduces the gain of the IF amplifier to minimize circuit overload and signal distortion. When very weak signals are received, the AGC adjusts the gain of the IF amplifier for higher amplification.

The *demodulator circuit*, sometimes called the *detector*, follows the IF amplifier. It removes the carrier and recovers the desired information signal. From there, additional processing takes place to either boost the signal level or to shape it before it appears at the output.

Most receivers that we are familiar with have a speaker as the primary output. But there are exceptions, such as the picture tube in a TV set or the motor in a garage door opener. The receiver may also put out digital data that goes straight to a computer.

Transceivers

Most communications systems use both a transmitter and a receiver. In two-way radio, both send and receive capability is needed at both ends of the communications channel. Therefore, the receiver and transmitter are packaged together in the same housing to create a transceiver. Small portable transceivers are called hand-helds, walkie-talkies, or cellular telephones.

The transmitters and receivers are typically the same as those described earlier. However, in some cases, the transmitter and receiver may share circuits. They virtually always share the antenna and a common power supply like a battery. In some cases, a single-frequency synthesizer may generate both the receiver LO signal as well as the transmitter carrier.

ISM Band Transceiver

The ISM band refers to specific frequencies set aside for wireless industrial, scientific, and medical (ISM) applications. The most common frequencies in the United States are 315, 433, and 915 MHz. The frequency 868 MHz is widely used in Europe. These unlicensed frequencies are used for simple monitor and control applications using low-speed digital data over short ranges. Some common examples are garage door openers, remote keyless entry on cars, remote thermometers, tire pressure gauges, security and fire alarms, home automation, and any telemetry or remote control application. The radios used for this are typically single ICs to which an antenna, a battery, a housing, and the input data are added. The devices are available as a receiver, a transmitter, or a complete transceiver. Figure 7.13 is a block diagram of a typical transceiver.

The transmitter section uses an external crystal to serve as the reference to an internal PLL frequency synthesizer to set the frequency. The PLL actually multiplies the crystal frequency by some N value to get the desired output. If the crystal frequency is 6.77 MHz and the divide ratio is 64, the output would be 433.28 MHz. The serial digital data input coming from a sensor, an analog-to-digital converter (ADC), or a computer frequency modulates the crystal oscillator to create the FSK signal. A power amplifier (PA) after the transmit VCO boosts the power up into the 1- to 100-milliwatt range. The output goes to the antenna. A transmit/receive switch allows the antenna to be shared in a half-duplex system.

The receiver is a special version of a superheterodyne. The input signal from the antenna is boosted in amplitude by the LNA and applied to the mixers. The local oscillator is set to the incoming signal frequency (also the transmit frequency), so the mixers generate a difference of zero. This is called *direct conversion* or *zero IF*. Two mixers are used and the local oscillator is shifted 90 degrees in phase between the two. This gives two zero IF outputs that are filtered. Zero IF does not mean a nonexistent output signal. It just means that the FSK signal is recovered directly at its data rate. The I and Q signals are 90 degrees out

of phase and this allows the digital data to be more easily demodulated. A data slicer, a circuit like a comparator, is used to shape the signal into a clean binary bit stream. With this kind of radio, the range is limited. It may be only a few feet or up to a mile or so depending on the antenna, environment, or application.

ANTENNAS

The antenna takes the voltage and current produced by the transmitter and converts it into the electromagnetic wave we know as a radio wave. At the receiver, the antenna converts the electromagnetic field back into a voltage we know as the radio signal. The radio waves pass over the receiving antenna, inducing a voltage that causes current to flow in the receiver.

Antennas can have an amazing variety of shapes. Essentially an antenna or aerial is some arrangement of electrical conductors whose size and length are critical. For optimum operation, the antenna length must be related to the wavelength (λ) of the signal. Common antenna sizes are one-quarter ($\lambda/4$) and one-half ($\lambda/2$) wavelength at the operating frequency. The higher the frequency, the shorter the wavelength and thus the smaller the antenna. For example, one wavelength at 150 MHz, a popular two-way radio frequency range measures 2 meters. A half wavelength is 1 meter and a quarter wavelength is 0.5 meter. Since 1 meter is 39.37 inches, a half wavelength is 19.68 inches. At 900 MHz, the frequency range of cell phones, one wavelength is 0.3333 meter. A quarter wavelength antenna would be $0.3333/4 = 0.08333$ meter or 3.28 inches.

Ground-Plane Antenna

Antennas can be anywhere from a long horizontal copper wire to a vertical steel or aluminum tower several hundred feet tall. Or it may be an array of short conductors like those in a TV antenna. One of the most common antennas is a short quarter wavelength vertical that is widely used in mobile radios, cell phones, and other hand-held units (see Figure 7.14). The quarter-wave or ground-plane antenna as it is sometimes called, radiates equally well in all directions, making it omnidirectional. We say that its radiation or reception pattern is a circle.

Dipole

Another common antenna type is the dipole, which is one-half wavelength long and usually mounted horizontally. Figure 7.15 shows an example. Its radiation or reception pattern is a figure 8. The greatest radiation or strongest reception occurs at a right angle to the dipole element itself.

Yagi

A variation of the dipole is the Yagi, a multielement antenna based on the dipole shown in Figure 7.16. To the dipole is added a reflector element that is

slightly longer than one-half wavelength, and one or more director elements that are progressively shorter than the dipole. The directors and reflector make the Yagi highly directional. The extra elements, called *parasitic elements*, concentrate and aim the beam of radiation over a narrow range. At the transmitter, this has the effect of increasing the transmitted power, making the signal stronger at the receiver as if the transmitter power had been increased. A similar gain effect occurs at the receiver.

Other Antennas

There are many other antenna variations. Antennas formed with copper patterns on a printed circuit board (PCB) are widely used. One example is the *patch antenna* (see Figure 7.17). It is simply a square area of copper about one-half wavelength on a side made on a PCB. Another is the *loop antenna* that is just a loop of copper on the PCB. A popular cell phone antenna is the

inverted F, which is an F-shaped pattern on the PCB. Antennas also come as components. For microwave frequencies, there are special antennas made on a ceramic base that are small and can be soldered to a PCB.

Transmission Lines

The antenna is usually connected to the transmitter or receiver by way of a coaxial cable (see Figure 7.18). It consists of a copper center conductor surrounded by an insulator, such as Teflon. Around that is a shielded copper braid or foil. The whole thing is covered with a plastic insulator. Coaxial cable is the most commonly used transmission line to connect the equipment to the antenna. It provides an efficient method of transferring the voltages and currents to and from the antenna while providing a certain amount of shielding from noise. For PCB antennas, the transmission line is just a short pair of copper lines from the transceiver IC to the antenna.

Microwave Antennas and Waveguides

Antennas used at microwave frequencies are quite different from those used at the lower frequencies. Perhaps the most common is the *horn antenna*. It looks

like the flared end of a musical horn, only most of them have an opening or aperture that is rectangular rather than round.

As seen in Figure 7.19, the horn is directional and has gain. The microwave energy is fed to the horn by a transmission line. Coax can be used for the lower microwave frequencies, but at the higher microwave frequencies, coaxial cable loss is too high for long runs. A high percentage of the signal power is lost in the coax cable itself. This problem is overcome by using a waveguide. A waveguide is nothing more than a hollow copper pipe, usually with a rectangular cross-section through which the microwave energy passes from transmitter to antenna or from antenna to receiver.

The most effective and widely used microwave antenna is the parabolic dish (see Figure 7.20). This is usually a horn antenna combined with a reflector shaped like a dish. Its shape is a mathematical parabola. Signals transmitted by the horn are reflected forward by the parabolic dish shaping the radio waves into a very narrow beam. Received energy is reflected by the dish into the horn antenna. The highly directional nature of the dish gives it a very

narrow beamwidth and enormous gain. These are widely used in satellite TV and radar.

TWO-WAY RADIO

Two-way radio communications between individuals are by far the most widespread use of radio. And there are many forms of it. You have seen such radio communications as they take place and you have no doubt engaged in some form of it yourself. In any case, this section takes a look at some of the diverse uses of such two-way communications.

Most two-way radios operate in the VHF and UHF bands. The simplest two-way radios operate on multiple frequencies usually selected by a frequency synthesizer. Virtually all two-way radio communications are half duplex, meaning that one party transmits while the other receives.

Aircraft

All airplanes from the smallest single-prop planes to the largest jumbo super jets use two-way radio to communicate with airport towers and the major air traffic management centers across the country. Two-way radio is absolutely essential to the safety of any flight.

Most aircraft radios are transmitters installed in front of the pilot or co-pilot. They usually operate in the 108- to 135-MHz band and use amplitude modulation (AM). Specific channels are assigned for different regions and for different communications functions. The pilot or co-pilot uses front panel switches to select the desired communications frequency. Hand-held microphones with a push-to-talk switch are the most commonly used input devices, but other forms of microphones such as throat mikes or microphones attached to headsets are also widely used. Most transceivers operate at very low power and transmission distances are considerable. The height of the airplane gives the radio transceiver an enormous transmission range even with low power at VHF frequencies.

Citizens Band

You have no doubt heard of citizens band (CB) radio and perhaps even used one yourself. Anyone can buy and use a citizens band radio for two-way communications. The FCC has allocated 40 frequencies or channels in the 27-MHz frequency range for citizens band operation. The maximum transmission power is restricted to 5 watts, although some hand-held units use less. AM is used.

Citizens band radio has enjoyed wide popularity with individuals and sportsmen as well as truckers. While the advent of the cellular telephone has reduced the number of individuals using citizens band radio, it is still widely used. The primary limitation of most CB radios is the antenna. Since CB radios operate in the 27-MHz range, the required minimum antenna length is approximately 9 feet. This can be shrunk somewhat by the use of coils attached to the antenna, but effectiveness is reduced. A CB radio antenna of 5 or 6 feet is common and certainly manageable on a car, truck, or boat. In hand-held transceivers, any antenna longer than about 18 inches is a nuisance.

A 27-MHz frequency allocation of CB radio also gives it some peculiar transmission characteristics. While communications is reliable over short distances of up to several miles, at certain times of the day or evening, worldwide communication is also possible. This is probably more a disadvantage than an advantage, primarily because interference can be received from stations literally anywhere in the world.

Amateur Radio

Amateur or ham radio is a hobby. Technically knowledgeable individuals are licensed by the FCC to use selected frequency bands across the spectrum for personal communications. Hams use voice as well as CW (continuous wave) or Morse code transmissions. Hams talk to one another about their equipment, the weather, and other common matters. Communication is worldwide and helps to promote good international relationships. Hams frequently design, build, and experiment with their own equipment, although many hams prefer commercially manufactured radios. Hams experiment with digital radios, satellites, and TV.

Family Radio

Family radio is another radio service recently instituted by the FCC for the purpose of short-range personal communications. It supplements CB radio in a wide range of personal communications needs. Because of a different frequency allocation, family radios are smaller, more portable, and have more reliable communications over distances of several miles.

All family radios are hand-helds using FM and operating in the 450-MHz range. Only several frequencies in the 450 MHz band are allocated to the Family Radio Service. While many users will share these frequencies, the short communication distances minimize interference between stations using the same frequency. The transceivers are restricted to 2 watts in power. At a frequency of 450 MHz, a quarter-wave whip antenna is only about 6 inches long. Communications are extremely reliable up to 1 mile and even farther if transmission takes place outdoors.

You can use family radios in a variety of ways. They are particularly handy when you are camping, hiking, or doing other outdoor activities. Many families use them in shopping malls and even around the house to keep in touch. They are great on farms and ranches and for communications between two nearby cars.

Marine

The very first application of two-way radio in the world was on ships at sea. Ships were always in danger without any form of communication. If a ship was disabled or began sinking, no one would know for a long period of time or maybe never. With a two-way radio or even a one-way radio on a ship, the operator could communicate with a shore-based radio station to signal danger with the familiar SOS.

Today, a radio is a necessity on virtually every boat and ship. While small boats are not required to carry radios, most larger boats are. And what seaman would be without a radio for safety reasons?

Marine radios have operated on a wide range of frequencies over the years. Ocean-going liners have operated on shortwave frequencies so that long-distance communications are possible. Ships also operate on lower frequencies for exchanging messages and at the higher frequency for reliable communications near land and in port.

The typical marine radio for communicating near ports is a transceiver of 25 to 40 watts of power operating with frequency modulation in the 150- to 170-MHz range. Most of these units transmit on multiple frequencies, making it always possible to find a clear channel. Channel 16, operating on a frequency of 156.8 MHz, is used for emergency calls. This frequency is typically monitored by other boaters and always by the Coast Guard.

Mobile Radio

Mobile radio refers to two-way radios mounted in cars and trucks. These are widely used by police, fire, and other civil services. They are also widely used by taxis, buses, and by companies using fleets of cars or trucks for convenient communications. The typical unit is mounted in the vehicle and provides relatively high power in the 25- to 50-watt range. Most communications take place in the 150- to 170-MHz range. Other mobile radio frequency ranges are 450 to 470 MHz. Most radios today are hand-held types.

SATELLITES

A satellite is a space station that is designed to orbit the Earth and provide a remote radio signal relaying station for the purpose of extending the range of communications worldwide. See Figure 7.21. Such communications satellites contain both a receiver and transmitter that operate simultaneously. The receiver picks up signals from the Earth on one frequency and retransmits them simultaneously on another frequency. In this way, the transmitter and receiver in the satellite do not interfere with one another.

Most communications satellites are geosynchronous. These are satellites positioned to orbit directly around the Earth's equator at a distance of 22,300 miles from Earth. When located in this position, the satellite rotates in exact synchronization with the Earth's rotation. Thus, the term *geosynchronous*. Because the satellite and the Earth are rotating together, it appears as though

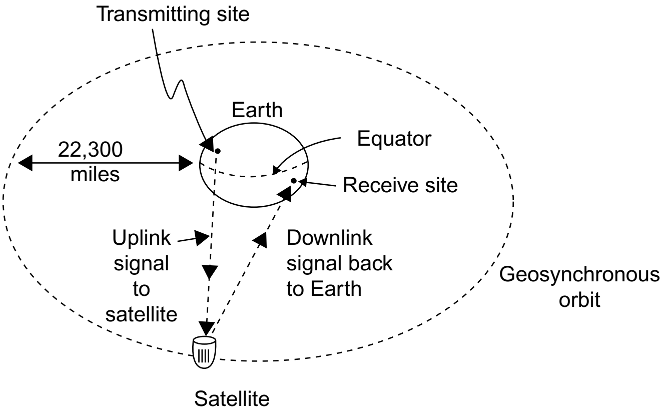

FIGURE 7.21 Concept of communications satellite.

the satellite is stationary overhead to an observer on Earth. With the satellite in a fixed position with respect to the Earth, the satellite becomes a near-perfect radio repeater station.

Figure 7.22 shows a general block diagram of a satellite. The communications part of a satellite consists of a combined receiver and transmitter called a transponder. Satellites operate in the microwave region. The C band from 4 to 6 GHz and the K_u band from 11 to 18 GHz are the most popular operating ranges. A low-noise amplifier (LNA) picks up the very small 6 GHz uplink signal from Earth. It is mixed with a 2-GHz LO signal and down-converted to a 4-GHz downlink signal, which is then amplified by a high-power amplifier (HPA) and retransmitted back to Earth. Most satellites contain many transponders with wide bandwidth capable of handling many signals simultaneously.

The satellite power source is batteries combined with a system of solar cells. The solar cells convert light from the Sun into electrical energy that is used to recharge the batteries. This system gives the satellite long life in space.

Communications satellites are used primarily in long-distance telephone communications and for distribution of TV signals. Some satellites are used for navigation, a good example being the global positioning system (GPS) widely used by the military and commercial organizations. It is also widely used by individuals as they find their way with personal navigation devices (PNDs) like those from Garmin and Tom Tom. The GPS system uses 26 satellites about 10,800 miles above the Earth orbiting in overlapping patterns so that at least three of four are “visible” by wireless at any point on the Earth.

Other satellites are used for surveillance. Spy satellites only 102 miles high pick up radio signals as well as infrared images and photographs. Weather satellites monitor cloud formations and movements. There are also two satellite telephone networks with low-Earth-orbit satellites to permit communications to/from any point on the planet.

RADIO TELESCOPES

Observation of the planets and stars is usually done with an optical telescope. However, in 1932 researchers discovered that distant stars or suns emitted radio waves. All stars, like our Sun, emit radio frequencies. Most of this energy occurs in the microwave region at 1.4218 GHz. This is the frequency of ionized hydrogen. By building a highly sensitive radio receiver and coupling it to a large highly directional radio antenna, it is possible to plot the position of distant stars just as effectively as an optical telescope. Radio telescopes are, in fact, even more effective in that they can more easily detect distant stars that cannot be seen even by the best optical telescopes.

Radio astronomy observatories consist of an enormous parabolic dish antenna usually 60 to 250 feet in diameter, which can be rotated and tilted so that it scans the skies. An array of multiple smaller dishes can also be used as in the SETI (search for extraterrestrial intelligence) project in New Mexico. The antennas are coupled to one or more very sensitive radio receivers. These

receivers have very high gain so that they can sufficiently amplify very small signals received from stars that are many light years away. Often special cooling systems are used to reduce the temperature of the receiver front end to minimize noise, thereby permitting even weaker signals to be received. The largest radio telescope is a parabolic dish reflector built of screen mesh 1000 feet in diameter. The dish is built into the valley between adjacent mountains near Arecibo, Puerto Rico. The horn antenna is moveable on a long cable so it can be positioned to see any part of the sky.

Wireless Everything

It seems like everything is going wireless these days. Cordless telephones, wireless local area networks, and your TV remote control. But wireless has always been around just not by that name. Most radio applications are old and well known. A few examples you may have encountered follow.

Garage door opener. A tiny transmitter in your car transmits a binary coded message to the receiver in your garage hooked up to the door motor.

Remote keyless entry. A miniature transmitter on your key ring transmits a signal to a receiver in your car that opens the door locks. Some even turn on lights and start your car from 10 to 30 feet away.

Wireless data acquisition. Remote transmitters are set up with solar batteries at remote sites to gather data from sensors and transmit it back to a collection center. A good example is electric, gas, and water utilities that use such systems to monitor critical conditions at remote sites and transmit the data back to a central monitoring facility where decisions can be made. Home wireless thermometers are very common.

Radio control of models. This is very common in toy cars, model airplanes, and boats.

RFID. Ultra miniature radios are being embedded in shipping labels, cars, and other objects for identification purposes. The units transmit their unique ID code when scanned by a nearby receiver.

HD radio. This is digital radio broadcasting in the United States. Most U.S. AM and FM stations now transmit a digital version of their signals on the same frequencies as their analog transmissions. They use a form of digital modulation called OFDM (see Chapter 8). It produces greater frequency response than the regular analog broadcasts, making AM sound more like FM and FM sound more like a CD. A special radio is needed to receive it. The digital technology makes noise and fading less of a problem. And it permits each station to add several additional channels thanks to the multiplexing capabilities of the HD technology.

Security tags. The plastic tags clipped on new clothes to prevent their being stolen contain a tiny antenna and electronic circuit that make their presence known at a nearby transmitter/receiver unit.

Surveillance and bugging, or secret monitoring or electronic spying. This is not just something you see in the movies or on TV. It is more widely used in private investigation, police work, and industrial espionage than you may think. Scary.

Face it, wireless is truly everywhere.

Project 7.1

Investigate HD Radio

HD radio is digital radio in the United States that shares the same frequencies as the regular AM and FM bands. You can buy stand-alone HD receivers, and some stereo receivers include it. HD radio is also available in some cars. To learn more about this technology, go to the website of the developer iBiquity or www.ibiquity.com. Also try a Google/Bing/Yahoo search on HD radio.

Project 7.2

Become Familiar with ISM Radio

ISM radio is the term used to refer to short-range data radios used in the FCC's unlicensed spectrum designated for industrial-scientific-medical (ISM) applications. Got to the FCC website www.fcc.gov and find the most commonly used ISM frequencies of operation in Part 15 of the rules and regulations. Do a general search of ISM to determine some common applications.

Project 7.3

Radar

Radar (radio detection and ranging) is a type of wireless. It has many uses, mainly military but also commercial and civilian. Marine and aircraft navigation are key applications. Police radar is widely used. Radar is also showing up in automobiles as detectors of distance between vehicles for automatic braking. You may wish to learn more about this technology. Do a search on radar.

Project 7.4

Shortwave Radio

Buy a low-cost shortwave radio and experience listening to international broadcasts and amateur radio operation.

Project 7.5

Experience CB or FRS

Go to your local Radio Shack and buy a pair of Family Radio Service walkie-talkies. Then test them to determine maximum range. As an alternative, buy a CB radio and listen to what is going on with the truckers or other locals.

Cell Phones

It Is Now Possible to Do Anything Wirelessly: Talk, Text, Email, Web Browse, Games, Whatever

In this Chapter:

- How the cellular system works.
- Cell phone radio technologies.
- Digital modulation and access schemes.
- Cell phone data capabilities.
- Smartphones, femto cells, MIMO, and location technology.

INTRODUCTION

The cell phone is one of the coolest, most useful, and convenient electronic devices of all time. It also happens to be one of the most complex technically, not only internally but because it is part of the largest communications network in the universe, the telephone system. The reason for a separate chapter on this topic is not only because of the advanced wireless technology involved, but also its importance to all of us personally and to the national economy. Since practically everyone has a cell phone today, it plays a huge role in our lives. And for you techies out there, it is worthwhile knowing a bit of the details of how phone calls work, how text messages get sent, and how you can now access the Internet via your cell phone.

CAN YOU HEAR ME NOW?

We've all said that before. Why? For one simple reason: cell phones are two-way radios with all the usual faults. The cell phone industry usually refers to itself as the wireless industry, but it's all the same thing—radio. Your cell phone contains a *transmitter* and a *receiver* that collectively are called a *transceiver*. You will also hear them called *handsets*. People in the industry also call them *mobile terminals*. Whatever. Because cell phones have to be so small to be practical, they are limited in the amount of power they can transmit and the type of antenna that is practical. Battery drain is a major factor in cell phone design, as you want to get as much talk time as you can on a battery charge. But by limiting the transmit power you automatically minimize the distance

over which the unit will transmit. In any case, communications range is related to power as well as antenna type and orientation. And the typical range of a cell phone is a mile or so, depending on conditions. Take a look at the sidebar to review some of the facts about wireless and radio covered in Chapter 7.

Factors Affecting Range and Reliability to Radio Transmission

Range—The greater the distance between any transmitter and receiver, the smaller the signal. Signal strength varies inversely by the square of the distance between transmitter and receiver.

Power—The higher the power the greater the transmission range. More power translates into increased communications distance up to a point.

Antenna gain—Some antennas focus the signal in a specific direction. Doing so gives the antenna *gain*, meaning it multiplies the power of the transmitter and the signal strength at the receiver.

Environment—Cell phones and any other microwave wireless device always transmit farther in clear open space. The ideal is direct line of sight (LOS), meaning that the two antennas can "see" one another. While cell phones don't have to have such a clear path to work, they always work better if they do. Environment also means transmitting from inside a building. Yes, radio waves do pass through walls and other obstructions but as they do they lose considerable strength as they encounter obstacles. Walls, ceilings, floors, and any other obstructions greatly attenuate (make it smaller) the radio signal. So if you are inside a car, shopping mall, office, or airplane, your signal strength loses over half its strength and that severely restricts your range.

Height—Getting your cell phone to the highest possible point will greatly increase transmission distance. This helps the line of sight effect so important to reliable transmission. Getting higher typically isn't practical, but almost nothing helps more than height, especially outside.

Receiver sensitivity—This means how much gain the receiver has. High gain translates into greater range.

Multipath—Whenever you are transmitting in an environment with lots of obstructions, your signal will bounce off many objects and be reflected. Some reflected signals will get lost and never get to the receiver. Others will bounce off objects that will ultimately direct them to their intended destination. These reflected signals will be delayed in time. Depending on factors such as operating frequency and distance traveled, these signals could arrive in phase and actually boost reception level. Or they could arrive out of phase and literally cancel the more direct signal that arrived earlier.

Noise—Don't forget that noise also affects communications distance and reliability. See discussion in Chapter 7.

THE CELLULAR CONCEPT

The original designers of the cell phone created a system that helps overcome the range and power problem described in the sidebar. If distances are kept

short, then other limitations in power and environment are offset. The working word here is "cell." A cell or cell site is one of many transmit/receive stations set up to communicate with individual cell phones. Also known as base stations, these facilities are easily recognized by their tall antenna towers. The small building at the base of the tower houses racks of transceivers that share the big antennas at the top of the tower. Long coax cables carry the signals to and from the antenna. They actually look like pipes going up the side of the tower.

Cell phone systems have dozens to hundreds of cell sites. An ideal design is shown in Figure 8.1A. Each cell represents an area covered by the base station antennas. Cell range and overall coverage are deliberately restricted by antenna height and radiation pattern as well as transmitting power. The hexagon-shaped cells are only theoretical. In reality, the shape of the cell is more circular or rather an irregular circular shape because of antenna characteristics and environmental characteristics that affect the cell shape (nearby trees, buildings, etc.) (see Figure 8.1B).

While equal-size cells are desirable and operation more predictable, in the real world, the coverage of each cell depends a great deal on the number of cell phone subscribers as well as the terrain and environment. In large cities with lots of people and buildings, smaller cell sizes are used to increase subscriber capacity and provide the most reliable coverage possible in a given area. Many cities have what are called microcells that may only cover one block or picocells that cover one area of a building. On the other hand, in rural areas and along

Larger rural site

FIGURE 8.2 How small and large cells cover an area.

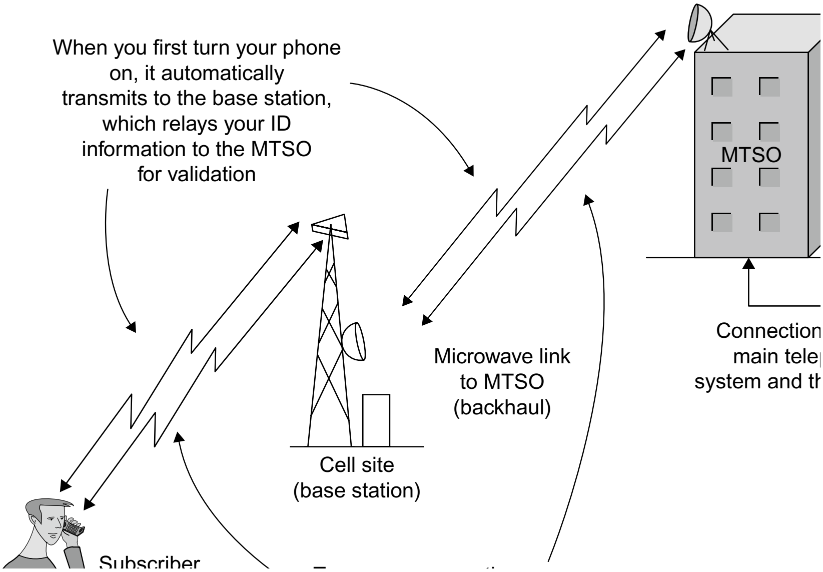
major highways, the cell sizes are larger and cover fewer users. The cell coverage may look more like that in Figure 8.2.

A key feature of the cellular concept is that by keeping the cell sizes small, the frequency channels assigned to cellular service can be reused. One frequency may carry different calls if the cell sites are far enough apart and do not interfere with one another. This frequency reuse concept multiplies the overall number of channels available to handle calls.

One other factor to keep in mind is that in most cities, there are two or more cellular companies vying for your business. Each company has its own cellular system with base stations with coverage that overlays the cell coverage of other companies. The competing systems do not interfere with one another because they usually operate on different frequencies with different radio technology, and the cell phones they support know which base stations to talk to.

One other thing: when you are talking on your cell phone, you are talking to only one base station—typically the one closest to you since both the power and range of your handset and that of the base station are limited. If you are moving (such as in a car), you will eventually leave the coverage area of one cell and enter the coverage area of an adjacent cell. You never really know when this happens, but it is a pretty neat technical trick to make this happen. The process of having your call transferred from one cell site to another automatically is called the *hand-off*.

All of the base stations are tied to a central office known as the *mobile telephone switching office* (MTSO). Many companies simply refer to it as the *switch*, as its main job is switching between base stations as well as linking to



When you first turn your phone on, it automatically transmits to the base station, which relays your ID information to the MTSO for validation

the main telephone system. The connection between the base stations and the switching station can be by copper cable or fiber optic cable or in many cases by a separate microwave wireless link. This is known as *backhaul*. If a cell site tower has one or more small "dish" antennas on it you can bet that your signal eventually is communicated back to the switch via another wireless link.

The big job of the MTSO is to control and keep track of everything. It validates you as a subscriber when you turn on your phone and make a call. It keeps track of how many minutes of time you use. And it will get messages from remote switches when you are in the roam mode outside of your usual home subscriber area. The cell phone companies have the ability to use other systems in most major cities and in many foreign countries, so you can use the phone virtually anywhere. Figure 8.3 shows just what goes on when you turn on your phone and make or receive a call.

WHAT'S INSIDE A CELL PHONE?

A cell phone can legitimately be called the world's most complicated two-way radio. Sure, it is just a transceiver, but it uses practically every radio trick in the book to ensure that you can make your calls reliably anytime with minimal hassle. It is a two-way radio that is used just like any other phone you are familiar with. In other words, you do not have to say "over," "come back," or any other phrase when you are finished talking and want to listen, as with some two-way radios (CB, family radio, ham radio, aircraft, marine, etc.).

Simultaneous send and receive is referred to as *full duplex*. All telephones are full duplex. It is easy to do in the wired telephone system but complex and costly to do by radio. Yet, full duplex is what makes cell phones so comfortable to use. There is none of this “roger and over” stuff. What this means is that your transmitter and receiver are working at the same time. There is more about how duplexing works later.

Figure 8.4 shows a general block diagram of what’s in a cell phone. The receiver and transmitter making up the transceiver are obvious and they share the single antenna. The transceiver is usually a single chip. What is not so obvious is what we call the baseband part of the cell phone. Baseband refers to the voice and data to be transmitted or received. In most modern digital cell phones, this is a very complex integrated circuit that handles the translation of voice between analog and digital, modulation and demodulation, and voice compression. All these functions are done digitally by a digital signal processor (DSP) or special DSP circuits in combination with a powerful embedded processor. This processor or a separate processor handles all the transparent housekeeping jobs of managing the keyboard and the LCD screen as well as the basic control features of the cell system, which also include automatic operating frequency selection and automatic power control under the direction of the MTSO via the cell site. The DSP also implements the messaging functions.

What Type of Cell Phone Do You Have?

Shame on you if you don't know. Well, not really. Actually, it is tough to know just what type of cell phone you have. You can't tell by looking, even inside, since even if you open up your cell phone, God forbid, all you see is a group of integrated circuits, and you can't tell one from another. Furthermore, your cell phone carrier doesn't tell you and usually your user's manual never really says. You can probably ask by calling your carrier, but even then you may not get an answer. I guess the bottom line here is, do you really care? If it does what you want, what difference does it make what technology you are using? On the other hand, if you are an electronics geek, you want to know. I do.

So even though no one knows what type of phone you are using, it does impact the overall system and what phone features and capabilities you have. Multiple types of cell phone technologies are in use concurrently, and that is what makes the cell phone system so bloody complex and expensive. Most of the original carriers have to continue to support the older original technologies as well as implement new ones to stay competitive with other carriers offering their hot new data technologies and features such as email, instant messaging, games, Internet access, mobile TV, and the like.

The first characteristic of a cell phone is the frequencies it uses. Most cell phones operate in the 800- to 900-MHz band where there are hundreds of channels for cell phone calls. Another range of frequencies is the so-called personal communications system (PCS) band from 1850 to 1990 MHz (1.85 to 1.99 GHz), which has hundreds more channels. Some of the newer phones use the advanced wireless services (AWS), 1700- and 2100-MHz spectrum assignments. Because of the higher frequency, PCS and AWS systems have a shorter range, and thus use smaller area cells, which means many more cells sites to cover a given area. Some cell phones actually operate on two or more bands.

Next, a cell phone is known by the technology and access methods it uses. The early original analog phones used first-generation (1G) technology, or FM, but have now been phased out so that only second-generation (2G) digital phones are in use. We are now in the third generation (3G) of cell phone technology and 4G is almost with us. A summary of these technologies follows.

GSM—The Global System for Mobile Communications (originally called Groupe Spécial Mobile) is the 2G digital system developed in Europe. Now all of Europe, most of the United States, and the rest of the world use this excellent but seriously complex technology. It uses time-division multiple access (TDMA), a digital system using digital modulation and a method of multiplying the number of channels in a given amount of frequency spectrum. Your voice is converted to binary 1's and 0's before being transmitted. This allows the carrier to put eight subscribers in one 200-kHz-wide frequency channel, thereby greatly multiplying their subscriber capacity and income. GSM uses a form of FSK called Gaussian minimum shift keying (GMSK). Today, U.S. carriers ATT Wireless and T-Mobile use GSM. By going to

GSM, these carriers can take advantage of several enhancements that facilitate high-speed data transmissions such as the General Packet Radio System (GPRS) and Enhanced Data Rate for GSM Evolution (EDGE).

GPRS—This is an extension of GSM that gives users an always-on packet data transmission capability that they can use for email, Internet access, messaging, or games. GPRS steals one or more of the eight TDMA channels to transmit or receive data instead of digital voice. You can achieve a data rate of about 20 to 60 kbps. GPRS is known as a two-and-a-half generation (2.5G) technology, and is generally available in most larger cities.

EDGE—This 2.5G system is a software upgrade from GPRS/GSM systems that gives you even higher packet data rates. It uses a multilevel modulation called 8PSK that triples the speed of data transmission. Practical speeds up to 180 kbps are possible.

CDMA—Code division multiple access is another 2G digital cell phone technology developed by San Diego–based Qualcomm Inc. The basic technology is known as *spread spectrum* where many signals are transmitted simultaneously over a very wide 1.25-MHz frequency band without interfering with one another. The original standard is called IS-95, and CDMA signals coexist in the same spectrum with TDMA systems in many areas.

cdma2000—This is the 2.5G version of CDMA. It adds high-speed packet data transmission called 1xRTT with a data rate up to 144 kbps. A more recent upgrade called 1xRTT EV-DO has even higher data rates up to 2 Mbps, making Internet access a cinch. Many cdma2000 systems are in operation around the United States by Verizon and Sprint and in Korea.

WCDMA—This is wideband CDMA, which is a third-generation (3G) technology. The access technology is CDMA, but it uses wider 5-MHz bands to provide greater user capacity and very high potential data rates from 384 kbps to 2 Mbps. WCDMA is the upgrade from GSM/EDGE. Carriers using GSM upgraded their systems to WCDMA for greater data speeds and services at greater subscriber capacity. Base stations support both GSM and WCDMA.

HSDPA/HSUPA—High-speed downlink packet access (HSDPA) and high-speed uplink packet access (HSUPA) are upgrades from the WCDMA system. Both use QAM to boost data speeds in the same 5-MHz channels. Data rates as high as 14 Mbps down-link and 5 Mbps up-link are possible. Most cellular companies have now implemented this technology. More advanced versions called HSPA or HSPA+ can give even higher data rates.

cdma2000 Rev A and **Rev B**—These are more advanced CDMA versions that are used to boost data speeds in cdma2000 handsets. Rev A boosts download data rates to 3.1 Mbps using QPSK and 16-QAM in the standard 1.25-MHz channel. Rev B is not widely implemented, but can use three 1.25-MHz channels and boost download speeds to 14.7 Mbps.

Long-Term Evolution—Long-Term Evolution (LTE) is the next or fourth-generation (4G) cell phone technology. It is just now being implemented. It is appearing in Europe first and the United States later. It uses an entirely different radio technology called orthogonal frequency division multiplexing (OFDM) to give even higher data rates up to 100 Mbps. More on that later.

How can you tell which of the above phone technologies you have? You cannot tell by the manufacturer, such as RIM BlackBerry, Samsung, LG, Motorola, Nokia, Sony Ericsson, and so on, because they all make multiple types. However, a few clues follow.

Carriers AT&T and T-Mobile provide GSM/WCDMA phones. Most also have some form of HSPA. These carriers will eventually morph their systems to LTE. Carriers Sprint and Verizon use cdma2000 phones. Most phones today are also what we call multimode phones in that they incorporate two or more different technologies. The most common combination is GSM/WCDMA/HSPA.

DIGITAL MODULATION AND WIRELESS TRANSMISSION METHODS

In Chapter 7, basic digital modulation methods ASK/OOK and FSK were covered. These are not used except for an advanced FSK as used in GSM. Instead, all cellular systems used advanced digital modulation methods. This section provides a look at these techniques.

Quadrature Amplitude Modulation

Quadrature amplitude modulation (QAM) is a technique that mixes both amplitude and phase variations in a carrier at the same time. What this technique does is to allow higher data rates within the same bandwidth. See the sidebar on spectral efficiency. The technique consists of transmitting multiple bits for each time interval of the carrier *symbol*. The term "symbol" means some unique combination of phase and amplitude. The term M as in M-QAM indicates how many bits are transmitted per time interval or symbol for each unique amplitude/phase combination.

The simplest form of QAM is 2-QAM, more commonly called QPSK or quadrature phase shift keying. It is produced by the circuit shown in Figure 8.5. It takes the serial bitstream and passes it through a 2-bit shift register producing two parallel bitstreams at half the rate. One is called the in-phase (I) bitstream and the other the quadrature (Q) bitstream. The I and Q signals are each applied to a mixer along with a local oscillator (LO) signal. The mixer output becomes part of the RF carrier. Note that the LO signal is applied directly to one mixer, but is shifted by 90 degrees and applied to the other mixer. The term "quadrature" means shifted by 90 degrees. The two mixer outputs are AM

signals but at different phases. But when they are added together, the QPSK signal is generated. With this arrangement, you can transmit data at twice the rate of BPSK in the same bandwidth.

Figure 8.6 shows how we illustrate this with what we call the phasor and constellation diagrams. Figure 8.6A shows the amplitude and phase of each possible combination of 2 bits. The length of the arrow called a *phasor* is the amplitude, and its direction or angle is the phase. If the receiver gets a signal

that is at a phase angle of 135 degrees, it means that the 2-bit combination 01 is being transmitted. The constellation diagram in Figure 8.6B is usually shown without the arrows or phasors.

This technique can be modified to produce 16-QAM, which transmits 4 bits per time interval or symbol causing the data rate to quadruple in the same bandwidth. The circuit for producing 16-QAM is shown in Figure 8.7. The 4-bit shift register produces two groups of I and Q bits. These are converted into four levels by a two- to four-level converter that works like a digital-to-analog converter (DAC). The resulting constellation diagram for 16-QAM is shown in Figure 8.6 as well. Other common versions are 64-QAM and 256-QAM, which transmit 6 and 8 bits per symbol, respectively, in the same bandwidth.

QPSK and QAM modulation methods are common in cable TV for digital TV as well as high-speed Internet service. They are also used with satellites and any broadband wireless application. All modern cell phones and most other digital wireless schemes use this type of modulation because of its spectral efficiency.

Orthogonal Frequency Division Multiplexing

Orthogonal frequency division multiplexing (OFDM) is a broadband modulation method like spread spectrum/CDMA. It takes a high-speed serial binary

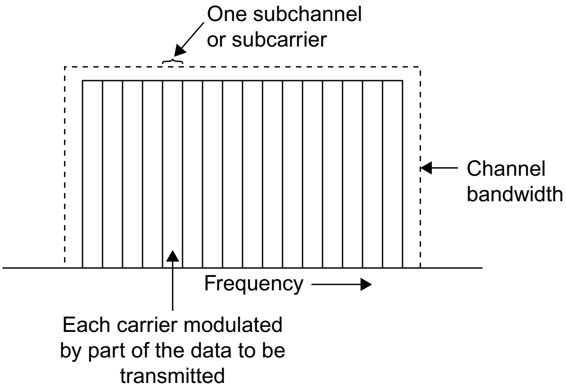

FIGURE 8.8 OFDM divides a channel into many subchannels or subcarriers, each of which is modulated by part of digital data to be transmitted.

signal and spreads it over a wide bandwidth. The serial data is passed through a circuit that maps out the constellation diagram for the modulation to be used. It then divides it into many slower-speed serial bitstreams. Each bitstream modulates a carrier on one of many adjacent carriers in the available bandwidth. This technique effectively divides a wide bandwidth into many narrower subchannels or subcarriers as shown in Figure 8.8. Sometimes dozens of channels are used, and in other cases hundreds or even thousands of carriers are used. The carrier frequencies are selected so they are orthogonal and as a result they will not interfere with one another even though they are directly adjacent. All the modulated channels are then added together and the combination transmitted in the available bandwidth. The type of modulation varies with the application but it is usually BPSK, QPSK, 16-QAM, or 64-QAM.

The basic technique is shown in Figure 8.9. The only practical way to create an OFDM signal is by using DSP. The DSP executes an algorithm called the inverse fast Fourier transform (IFFT) that creates the multiple adjacent modulated carriers. The DSP data is applied to DACs to create I and Q signals that are sent to mixers for creation of the final signal. At the receiver, the data is recovered by another DSP executing the FFT. The output is the original fast serial data.

OFDM seems impossibly complex while seemingly hogging spectrum space. Yet, it can transmit higher speeds in smaller bandwidths than most other types of digital modulation. It is very spectrally efficient. Furthermore, it is more resistant to multipath interference that can cause microwave links to lose data due to a reflected signal interfering with another or a direct signal causing cancellation and fading. Most of the new wireless technologies today use OFDM, including the forthcoming LTE cellular systems. Some examples of other OFDM uses include wireless local area networks (WLAN), wireless broadband (WiMAX), digital subscriber line (DSL) Internet access, digital TV, and AC power-line networking.

Multiple Input Multiple Output

Another technique for boosting speed within a given bandwidth is multiple input multiple output (MIMO). Also known as spatial multiplexing, it is the use of multiple transmitters transmitting to multiple receivers, each sending different bitstreams on the same channel. The high-speed serial data is divided into two, three, four, or even more bitstreams, and each is used to modulate a different transmitter but operating on the same frequency. The signals from each transmitter reach the antennas of each receiver along with any reflected signals. See Figure 8.10, which shows four transmitters (Tx) and four receivers (Rx) or 4 × 4 MIMO. What allows the receivers to sort out each bitstream is the fact that each signal travels a different path, and will have different characteristics or spatial signature that can be sorted out by DSP in the receiver.

There are several things that make MIMO practical. First, MIMO is used at very high frequencies, especially microwave (>1 GHz). This means that antennas are short and inter-antenna space may be one wavelength or more, which is required for MIMO to work. The distance between the antennas ensures different spatial paths with different characteristics that let the receivers recover each bitstream. Second, thanks to semiconductor technology, it is possible to make the multiple transmitters and receivers very inexpensively, typically all on a single silicon chip.

MIMO has several benefits. First, it allows a higher data rate in the same channel bandwidth. Using a 4 × 4 MIMO, for example, would boost speed by a factor of 4. Configurations of MIMO can be any combination of transmitters and receivers. The 2 × 2 mode is popular but 4 × 4 is also used. Second, MIMO provides a more reliable link. It actually takes advantage of the multipath problems that usually plague microwave wireless and makes it

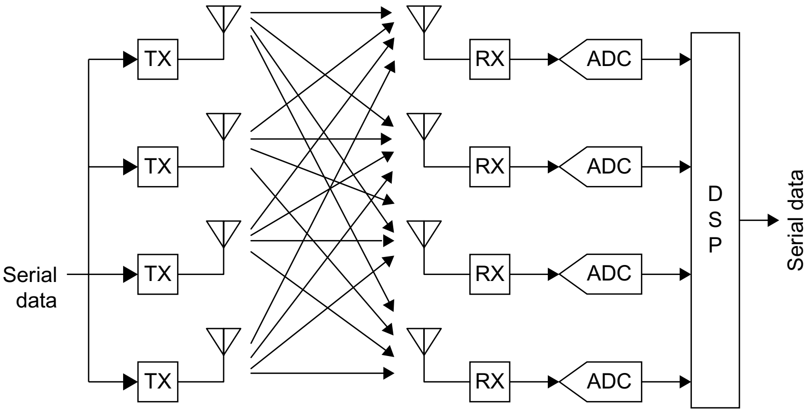

FIGURE 8.10 MIMO in a 4 × 4 configuration quadruples the data rate in an existing channel, while reducing the ill effects of multipath fading.

better. Finally, MIMO is usually combined with OFDM, which provides the ultimate data-rate boost, reliability, and spatial efficiency. MIMO is already used in wireless local area networks (WLAN) like Wi-Fi and in broadband wireless systems using WiMAX. Both of these technologies will be covered in the next chapter. MIMO will also be used with LTE, the next cell phone system. No, handsets probably will not have multiple antennas but the base stations will.

Spectral Efficiency

Spectral efficiency refers to how much data you can transmit in a given bandwidth. It is usually measured in bits per second per hertz (bps/Hz). ASK/OOK and FSK have efficiencies of <1. Special forms of FSK, such as Gaussian minimum shift keying (GMSK) used with GSM cell phones, are a bit better. BPSK has a spectral efficiency of 1. Table 8.1 gives the efficiencies of most of the popular digital wireless modulation schemes.

One last thing: the type of modulation is not the only thing that affects spectral efficiency. The level of noise in a channel also determines the number of bit errors that occur in transmission. The higher levels of QAM have more errors, so this limits their efficiency to some extent. Plain FSK, BPSK, and QPSK are very resistant to noise, so are more suitable in applications where noise is a problem. Noise and bit rates have to be traded off for good reliable transmission. And by the way, the spectral efficiency issue applies to wired as well as wireless communications channels.

ACCESS METHODS AND DUPLEXING

Access methods are wireless techniques that allow multiple users to share a given part of the frequency spectrum. Access methods are also called *multiplexing*. Multiplexing means allowing two or more signals to be transmitted *concurrently* over the same communications medium such as a cable or within a given frequency band. Access methods allow many subscribers to share precious spectrum space. And they provide the means to implement full-duplex simultaneous transmit/receive that most phone users expect. There are four types: frequency division multiple access (FDMA), time division multiple access (TDMA), code division multiple access (CDMA), and orthogonal frequency division multiplex access (OFDMA). For full-duplex operation, there are two methods—frequency-division duplexing (FDD) and time-division duplexing (TDD).

FDMA—A given bandwidth is divided into many narrower channels as shown in Figure 8.11. A given radio will cover all of the bands but has the ability to select a specific operating frequency. GSM divides the band into 200-kHz channels. cdma2000 uses 1.25-MHz channels and WCDMA uses 5-MHz channels. The newer OFDM uses 5-, 10-, 15-, or 20-MHz channels.

FDD—Simultaneous transmit and receive is accomplished by using two different bands where half are used for transmit and the other half for receive. The transmitter and receiver operate at the same time but on different frequencies so they do not interfere with one another (see Figure 8.11).

TDMA—With this method, a single-frequency channel is used, but the signal is divided into fixed-duration time slots into which digitized segments of voice or data are transmitted. In digital voice transmission, the analog voice

signal is periodically sampled and digitized into a stream of binary numbers. These binary values are then compressed into a smaller number of bits by a vocoder circuit. The resulting bits are then transmitted to the receiver. With TDMA, binary values from two or more voice sources can be interleaved and sequenced, and then sent over the single channel. For example, in GSM systems, there are eight time slots, as shown in Figure 8.12. The data is transmitted at a 270-kbps rate in a 200-kHz wide channel. Each time slot contains 1 byte of the voice data for one phone call. The frame of eight signals is then repeated.

TDD—Time-division duplexing facilitates concurrent send and receive by assigning transmitted signals in one time slot and received signals in another time slot. They share the same frequency channel. Because all this is happening at a high rate of speed, you cannot determine that transmit and receive are not simultaneous, although in reality they are not.

CDMA—This method uses spread-spectrum technology. It takes the digitized voice and further processes it to give it special coding, and then spreads it over a wide bandwidth. In cdma2000 phones, the channel bandwidth is 1.25 MHz wide, and all cell phone signals are coded and spread over this bandwidth. The process goes like this: the analog voice signal produced by the microphone is digitized in an ADC, and then compressed by a special digital circuit called a *vocoder* or *voice coder*. This reduces the total number of bits and the speed of the digital signal. This vocoded signal is then mixed with a high-speed serial code signal, making it unique so that the receiver will recognize it. This is done with an XOR gate as shown in Figure 8.13. The higher-frequency signal, at 1.23 Mbps, is called the *chipping data*. The resulting signal fills the 1.25-MHz channel. In WCDMA systems, the process is the same, but the chipping signal is 3.84 Mbps and the channel width is 5 MHz.

Many cell phone calls are then transmitted on the same channel. They actually all mix together, but because they occur randomly with one another, they do not interfere with one another. Typically, up to about 64 users can share the same bandwidth. One signal simply appears as a low-level noise to another. The desired signal is picked up at the receiver by recognizing the unique code given to the transmitted signal. The two most common types of spread spectrum are direct

sequence and frequency hopping. Direct-sequence spread spectrum (DSSS) is used in cell phones as illustrated in Figure 8.13. Frequency hopping is used in Bluetooth wireless systems (see Chapter 9). Most duplexing is by FDD, but some of the newer versions of WCDMA also use TDD.

OFDMA

Access with OFDM is done by just assigning one or more of the subchannels to each phone call. With each subchannel 15 kHz wide, each is capable of carrying a compressed (vocoded) voice signal so that many calls can be handled. In practice, more than one channel may be used, depending on the specific frequency assignments, bandwidths, and other features of the LTE system being used.

A LOOK INSIDE A 3G CELL PHONE

Figure 8.14 shows the insides of a modern 3G cell phone. This one uses the WCDMA/HSPA 3G technology, but is also backward compatible with GSM/EDGE if an area does not have 3G yet. There is a separate radio transceiver (XCVR) for each. All of the baseband functions like modulation and demodulation and handset management are handled by one or more processors. One processor may be DSP. This handset also has a Bluetooth radio for the headset (not shown) and a Wi-Fi transceiver for Internet access via a wireless LAN access point or hot spot. These technologies will be covered in the next chapter. A GPS radio provides navigation as well as fulfills the E911 requirement. Note that all radios have separate antennas. A camera in included. THE LATEST CELL PHONE TECHNOLOGY

The cell phone industry is one of the fastest changing in electronics. New products come out almost daily. And new features and capabilities are invented regularly to keep the technology fresh and the sales continuous. Here is a snapshot in time of the latest cell phone developments.

Smartphones

A smartphone is a basic cell phone but with advanced features that expand its use. The basic cell phone does phone calls or at most handles text messaging as well. But a smartphone has multiple functions. Some examples of smartphones are the BlackBerry models from Research in Motion (RIM), Apple's iPhone, some Nokia models, the Palm Pre, and various models from Samsung, LG, and Motorola. They are too numerous to mention and they go out of date monthly or yearly.

High-speed data capability. Most smartphones use 3G technology, so they can deliver almost as fast a data rate as your home Internet connections, usually 1 to 2 Mbps or better.

Internet access. A built-in browser lets you access the Internet just as you would from your home laptop. The main limitation is the small screen size, which prevents you from doing as much as you would like, but you can still do it.

Email. Email is one of the key features of a smartphone. It lets you stay in touch without a PC or laptop.

Messaging. It goes without saying that text messaging is a main data feature.

Digital camera. Most smartphones have an excellent high-resolution camera built in. It is not as great as a stand-alone digital camera, but it does have 1 to 3 megapixels of resolution.

Camcorder. Some of the digital cameras have video capability as well. The main limitation is the amount of memory available to store videos.

MP3/iPod. A music player is a standard feature of many smart phones. The key here is to have sufficient flash memory to store the songs you want.

Wireless local area network (WLAN) access. You will learn more about this in the next chapter, but a smartphone has a built-in separate transceiver to connect to a Wi-Fi hot spot or other access point in airports, hotels, coffee shops, and other locations just like a laptop. You can access the Internet or email as an alternative to doing it through the cellular network.

Bluetooth. Bluetooth is another short-range wireless technology covered in Chapter 9. It is used in smartphones for wireless headsets. A headset contains a headphone and a microphone that fits in the ear. It talks to the cell phone wirelessly via a Bluetooth link.

GPS. The global positioning system is the worldwide satellite navigation system. Many phones have a built-in GPS receiver so that you can find your way. Some even offer full navigation software and display as in those personal navigation devices (PNDs) like those from Garmin and Tom Tom.

Femtocells

One of the most frustrating problems cell phone users have is poor coverage at home. Many homes are not located near cell sites or have poor indoor performance. This is maddening to many, especially those who want to give up their regular wired home phone and go only wireless. One solution to this problem is the femtocell. This is a small base station designed to be installed at home. The concept is illustrated in Figure 8.15. It can usually accommodate calls from up to four cell phones. The femtocell connects back to the carrier via your high-speed Internet connection, a DSL line, or a cable TV link.

Femto cell
Cell phone

FIGURE 8.15 Concept of femto cell.

It provides great in-home coverage and has the added benefit that it offloads to the cell site and the carrier, providing more capacity to others.

Femtocells are just now becoming available but will soon be rolled out nationally. It is expected that the new LTE systems will make extensive use of femto cells.

Mobile TV

Video is now available on some phones. This video comes to you over the cell phone network, so it uses the high-speed data connection. Video is very data intensive, so it really loads down the network, limits subscriber capacity, and slows speed in some cases and raises your monthly bill. Yet, you can get various TV programs plus news, weather, sports, and comedy this way.

It has been decided that the best way to offer TV on a cell phone is to broadcast it directly to a small receiver in the cell phone. This keeps the video data overload off the cellular network and provides a better picture and more programming choices. This over the air (OTA) cell phone video is now available in many U.S. cities with more to come. A company and service called MediaFLO is transmitting TV to those who subscribe. Up to 15 or 20 channels provide a mix of programming. Some TV is also available in Europe using an OFDM system called Digital Video Broadcast-Handset (DVB-H). Variations are also available in Japan and Korea.

It is expected that some time in the near future, the U.S. digital TV system called the Advanced Television Systems Committee (ATSC) standard will be available in a mobile version that can be received via free OTA if the phone has a receiver built in. In all systems, the video is highly compressed using a standard referred to as H.264 and reformatted for a 360 × 240 pixel screen.

Location Technology

Location technology refers to systems and circuits that are designed to pinpoint the location of a cell phone in use. This can be done now to a certain extent, as a carrier can always determine which cell site a phone is currently using. That only locates the phone within an area of a few miles. The FCC has mandated that all cell phones can be located within 50 to 100 feet in case of an emergency. This is part of the E911 system for all cell phones. E911 means that your cell phone company has a system that will send your physical location to emergency services if you call 911 from your cell phone. Some systems use GPS, but others have another type of location technology. The whole thing is transparent to a user, and most users actually do not know that their phone has this capability.

The location capability has many concerned for privacy reasons. But if you don't want to be located, turn off your phone. Otherwise, learn to live with it, as it many save your life one day. Location technology is also supposed to lead to services that are based on location, such as advertisements for restaurants and other businesses near you.

When GPS is used, the GPS receiver computes your coordinates from the satellite signals and sends them to the carrier for use if called for. In another system, your location is determined by actually triangulating your phone with three nearby cell sites. No additional electronics are needed inside the phone, but special antennas, receivers, and other gear are needed at the cell sites. Both systems can usually pinpoint you within 50 feet or so depending on terrain and environment.

Project 8.1

Examine a Base Station

Go look at a cell site. The wireless phone company won't let you inside, but you can drive close to many and examine what you can see. Especially note the antenna arrangement at the top of the tower. Most have a triangular arrangement of three antenna arrays that divide the coverage into three 120-degree wide areas. You will see multiple coax cables going up the tower to carry the received and transmitted signals. Check for a dish that connects the site to the main switching station.

Project 8.2

Check Out the Latest Handsets, Features, and Services

Go to a cell phone store and ask about what digital services are available in your area. Try to find out what the technology is, such as GPRS, EDGE, cdma2000, 1xRTT, WCDMA, HSPA, and so on. Do you have email, instant messaging, games, Internet access, transmission of color digital photos, or what?

Project 8.3

Get an Area Coverage Map

Call your cellular carrier and ask for a coverage map. Some carriers actually give you this, but many times you have to ask for it. It may also be on your carrier website. The map will show you the actual range and coverage of the system. If you leave the area, you may have no coverage or you may switch over to another system in a roam mode.

Project 8.4

ID the Carriers

Identify the cell carriers (ATT Wireless, Cingular, Verizon, Sprint, Alltel, MetroPCS, etc.) in your area. If they advertise locally in the newspapers or in cell phone stores, they cover your area.

Project 8.5

Relevant Websites

There are several great websites where you can get additional information on how cell phones work. Here are a couple that I like: www.howstuffworks.com and www.sss-mag.com.

Networking: Wired and Wireless

All Devices Talking to One Another

In this Chapter:

- Types of networks defined: WAN, MAN, LAN, and PAN.
- Ethernet, Sonet, and other wired networking technologies.
- Internet transmission fundamentals.
- Wireless networking technologies, including Wi-Fi, Bluetooth, WiMAX, ZigBee, and others.

INTRODUCTION

You already know from reading this book that virtually every electronic product has a digital computer built into it in the form of an embedded controller or microcomputer. But one other fact about electronic equipment that you may not know is that a large percentage of these devices are now being interconnected to one another to form networks. This is particularly true of computers. After all, what computer today is not connected to some form of network? And while we may be nearing the point where all computers are networked, the trend continues toward networking many other non-computer devices. This chapter takes a look at networking concepts and the most popular forms of networks being used today, both wired and wireless.

IS EVERYTHING NETWORKED?

A network is just a system of people or things that are connected to one another. If someone was to ask you to give an example of a network, you probably would use the computer network definition. But there are all sorts of other networks in which we all participate in some form or another. One of the biggest networks is our interconnecting road system. Our highways and byways interconnect cities with one another and provide transportation routes for people and goods. The railroad is a massive network. You could also call the airline system a massive network of cities connected by airplane flights. Our whole electrical grid is a massive network. And one of the largest networks in

the world is the telephone system, both wired and wireless. And then again, let's not forget the Internet itself which connects us all to everything else. For our purposes here, our network definition is a system designed for communications via computers talking to one another or individuals talking to one another over cell phones. In all cases, a network is involved.

TYPES OF NETWORKS

There are lots of different ways to interconnect individual computers or other electronic products. You can do it by electrical cable or fiber optic cable or you can do it in a wireless manner. In any case, each computer or user in the network is called a *node*. The goal of a network is to connect each node to all other nodes in some way so that they can communicate. Over the years, several different levels of networks have evolved.

Wide Area Networks

A wide area network (WAN) is the largest network of all and we could consider the entire telephone network or the Internet as a large WAN. Sometimes WANs are smaller and may be localized to a country, a state, a city, or other large geographical area. The Internet is certainly a WAN. Most WANs are made up of fiber optic cable so that they can carry lots of data at very high speeds.

Metropolitan Area Networks

A metropolitan area network (MAN) is a network that covers a smaller geographical area such as a city or a large college campus system. Good examples of MANs are the local telephone company and your local cable TV company. MANs are also widely used in large companies and in governments to interconnect their computers. Most MANs are also implemented with fiber optic cable to maintain speed and data capacity.

Local Area Networks

A local area network (LAN) covers a small group of computers, typically a thousand computers or less. LANs are implemented in companies, small businesses, and even in homes. A LAN may only have a couple of users but could have several hundred, depending on the circumstances. Even two connected PCs at home comprise a LAN. In most cases, LANs are connected externally to a MAN or a WAN for external communications.

Personal Area Networks

Most personal area networks (PANs) are short-range wireless networks. A PAN is formed when two or more computers or cell phones interconnect to one another wirelessly over a short range, typically less than about 30 feet. Most PANs are what we call ad hoc networks that are only set up temporarily for a specific purpose. The Bluetooth headset option on a cell phone is an example of a PAN.

Home Area Networks

A home area network (HAN) is a network inside the home used to provide monitoring and control over energy usage. It connects to the utility's electric meter and monitors energy usage so the home owner can see what energy is being used and where. It is also used to give the utility a way to control the heating and air conditioning to save energy. The HAN also provides a way to conveniently turn appliances off and on. The HAN may use wireless or communications over the AC power line. The HAN is the home portion of the national Smart Grid effort to conserve energy.

Storage Area Networks

A storage area network (SAN), as its name implies, is a network that interconnects large data storage devices to computers and to one another. Large arrays of hard disks are usually set up to store massive amounts of data needed by business, the government, and other organizations. The SAN provides a way to access all this information in a fast and easy way.

Network Relationships

As it turns out, the different types of networks are connected to one another, the result being one massive network. Figure 9.1 is an example. For example, local

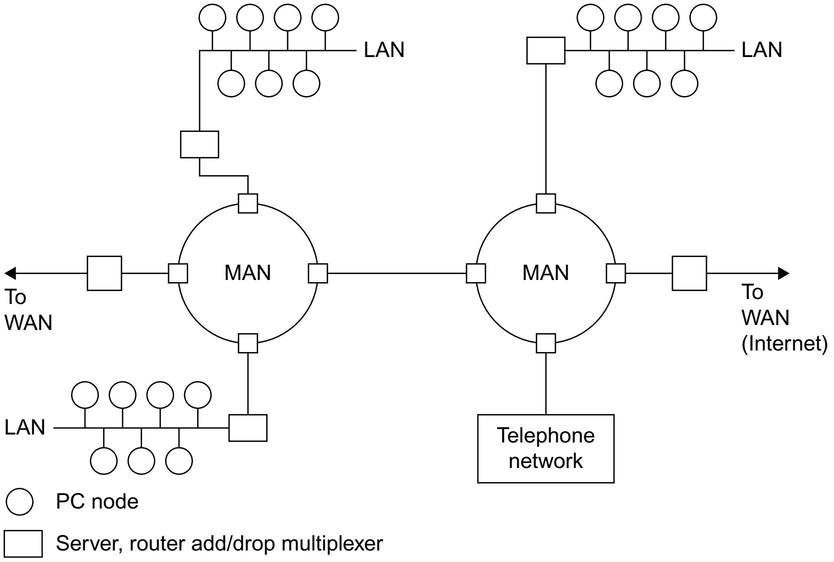

FIGURE 9.1 How LANs, MANs, and WANs connect to form a huge worldwide network of computers and other devices.

LANs are connected to MANs, while the MANs themselves are connected to WANs, and so on. In this figure, the circles represent PCs while the squares represent network connecting points. These include servers, the computers that manage LANs and MANs; routers, which determine connections in the network; and add/drop multiplexers that put data on the network and take it off. All the interconnecting links are fiber optic cable except for the copper cable in the LANs. This complex hierarchy essentially lets any computer talk to any other computer under the right conditions. The Internet implements such a hierarchy of networks.

NETWORK INTERCONNECTION METHODS

As you can imagine, there are lots of different ways to connect computers or other electronic devices to one another. For example, you could run a cable between each of the computers you want to interconnect. The result would be a large, complex, and very messy and expensive interconnection system. It is called a *mesh*. Except for a few computers, such systems are not used. Instead, over the years, several different interconnection methods called network topologies have emerged. These are the star, the ring, and the bus, all simply illustrated in Figure 9.2.

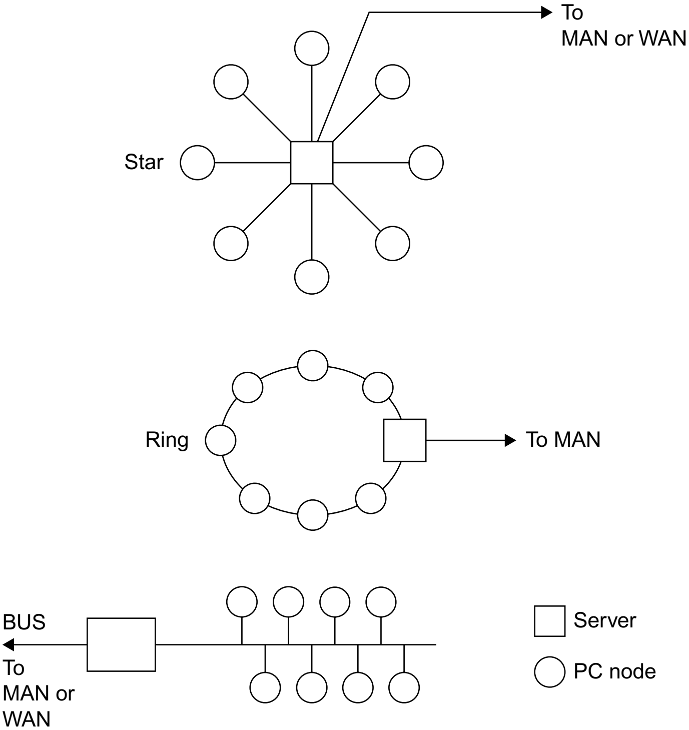

FIGURE 9.2 Three main networking topologies—star, ring, and bus. Bus is the most widely used.

In the *star* method, each node is connected to a central control computer or server that manages the interconnections from any PC to any other. In the *ring* interconnection, the computers are simply connected into a single closed loop. Then data is transferred from one computer to the next by sending it around the ring. The computer destined for the information will recognize it and grab it off the ring as it comes by. The *bus* method of interconnection is one of the most popular, as it is simply a common cable or connecting point to which all computers are attached. The problem with the bus is that there can only be one sender or transmitting party of the information on the bus at a time. This requires some method of managing who transmits to whom and when. All nodes can receive.

The mesh network mentioned earlier is a messy thing to implement with cables. However, it can be implemented wirelessly. In a mesh, all nodes can talk to all other nodes within their range. This is advantageous in that there are multiple paths for data to take if one path should be blocked for some reason. More on that later.

WIRED NETWORKING TECHNOLOGIES

Wired networks use three types of cable: twisted pair, coax, or fiber optic. The telephone system has used twisted-pair cable from the very beginning and it is still in use today. It is also the predominant way that LANs are interconnected. Coax cable was once popular but is not widely used today except in cable TV systems. Fiber optic cables were not practical until the 1970s, but since then have been developed into the best way to wire computer networks because of their high speed and low loss.

Types of Cables

Coax cable was the original networking medium (see Figure 9.3). It has a copper wire center conductor surrounded by an insulator like Teflon or another type of plastic, which in turn is usually covered with a wire-mesh braid.

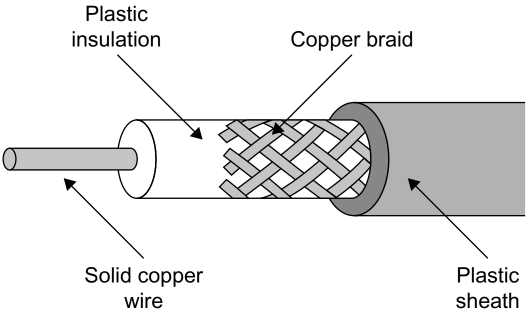

FIGURE 9.3 Coax cable. It is now mainly used in cable TV networks. The most common is RG-6/U and uses F-type connectors.

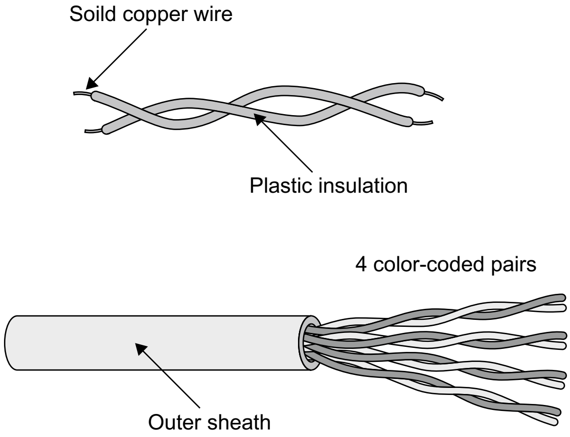

FIGURE 9.4 Twisted-pair cable. Initially used for telephones and is still used. Computer network cables use four twisted pairs. A shielded version is available where noise is a problem.

CAT6	10 Gbps	Ethernet LAN, video
CAT7	10 Gbps	LAN, point to point

A plastic outer jacket covers the whole thing. The center wire and the mesh are the two connection points. Coax can handle frequencies up to many gigahertz. But it has high losses over long distances. Coax is mainly used in cable TV networks.

Twisted pair is the widely used cable for telephones and LANs. It consists of two solid insulated wires twisted together as shown in Figure 9.4. Most telephone or LAN cables contain multiple pairs. Typical LAN cables have four pairs in a single cable. These cables are standardized and categorized as shown in Table 9.1. CAT5 and CAT5e are the most common. The eight wires are usually terminated in a connector called an RJ-45.

Fiber optic cable consists of a thin glass or plastic center piece surrounded by a plastic outer cover. Then that is further wrapped by an outer plastic covering (see Figure 9.5). Light waves are passed down the center glass or plastic cable. Most light comes from an infrared (IR) light laser. You cannot see IR but it is light nonetheless. IR light is what your TV remote control uses. The IR light is pulsed off and on to create binary signals. These are picked up

at the receiving end by a light detector and converted back into binary 0 and 1 voltages (see Figure 9.6).

Over the years, dozens of different wired networks have been developed. But in the past two decades, only two types of wired networks are dominant: Ethernet and Sonet.

Ethernet

Ethernet was originally developed as a LAN in the 1970s. It used coax cable in a bus topology to interconnect multiple computers. Ethernet is also known by its Institute of Electrical and Electronic Engineers (IEEE) standard designation 802.3. There are many variations of this technology, but the most common one uses unshielded twisted-pair cable. The bus topology is generally implemented inside a piece of equipment called a *hub* or *switch* (see Figure 9.7). The cable from each computer or other device is connected to one of the jacks on the hub or switch. The hub or switch connects to a master computer called a *server* that manages the network. Generally speaking, connections to the hub or switch are limited in length to about 100 meters or 300 feet.

The initial Ethernet LAN had a maximum data rate of 2.93 Mbps over coax. When Ethernet was standardized, the basic data rate was 10 Mbps. Over the years, Ethernet has been improved and developed to create versions with data speeds over twisted-pair cable of 100 Mbps, 1 Gbps, and 10 Gbps. While 10 Mbps can be implemented over a single twisted pair, to achieve speeds of 100 Mbps, 1 Gbps, and 10 Gbps, all four twisted pairs in the CAT5 cable are used. The data is divided between and transmitted in parallel at the same time using special multilevel encoding that permits such higher data rates to be achieved.

There are also versions of Ethernet that use fiber optic cable. Fiber optic cable is normally used on the 1-Gbps and 10-Gbps versions. The latest versions of Ethernet provide 40-Gbps and 100-Gbps data rates.

How Is Ethernet Used?

Ethernet uses a bus topology connection where only one node can transmit at a time. This requires the use of an access method that permits the nodes on

the bus to share it. Ethernet uses a technique known as *carrier sense multiple access with collision detection* (CSMA/CD). This is part of the IEEE 802.3 standard. Essentially what happens is that if a computer wants to transmit, it monitors the bus, and if no one is transmitting, it will begin transmitting its signal. If someone else tries to transmit at the same time, a collision occurs and both computers stop transmitting. Each will wait a random period of time and then try again. Whoever captures the bus first will be allowed to transmit. The data is transmitted over the bus and any computer connected to it can receive it. However, typically the transmission is only intended for one other computer. To identify that computer, each is given an Ethernet address that is transmitted along with the data to be sent.

The data to be transmitted are packaged together in a group of bits called a packet. Figure 9.8 shows what a typical Ethernet packet looks like. The preamble consists of 7 bytes of alternating 1's and 0's that help the receiving computer establish clock synchronization with the transmitting computer. The start frame delimiter presents a unique 1-byte code indicating that a frame of Ethernet data is to be transmitted. Next, a 6-byte destination address identifies the desired receiving node. The next 6 bytes identify the sending node. This is followed by another 2 bytes of data that indicate how long the data message is. The block of data is then transmitted. It can be any length from about 46 to 1500 bytes. The packet ends with a frame check sequence that is essentially a unique code designed for error detection and correction. If bit errors occur during transmission, the receiving computer can perform specific logic functions that allow the error to be detected and then corrected.

While Ethernet started out as a LAN, it has morphed into other larger forms of networks. Because of its high-speed capability with fiber optic cable, it is also used to form MANs and even WANs. A special version for MANs and WANs is called *Carrier Ethernet*. There is also a version of Ethernet used in storage area networks, called *Internet Small Systems Computer Interface* or *iSCSI*. There is also a wireless version of Ethernet that will be discussed in another section in this chapter.

Sonet

Sonet means *synchronous optical network*. Also known by its international standard name, *synchronous digital hierarchy*, this fiber optic network system was designed specifically for high-speed data transmission in telephone networks and computer systems. Basically, Sonet defines how data is transmitted over the fiber optic cables. This includes the data format as well as data speeds. Table 9.2 shows the various standardized transmission speeds from 51.84 to 39.812 Gbps. The bulk of Sonet installations, which are used primarily in the telephone networks and the Internet, use 2.488 Gbps (also generally called 2.5 Gbps) and 9.953 Gbps (generally referred to as 10-Gbps Sonet). More recently, new 39.812 (40) Gbps networks are being built for the Internet. Data is transmitted in fixed-length frames made up of 810 bytes, most of which is data. The network topology is either point to point or i n a ring.

Most big WANs and MANs use the Sonet system. However, Sonet is often used to transmit other data, including the telephone company T1 and T3 line data, asynchronous transfer mode (ATM), frame relay, and other telephone company formats. It is also widely used to carry Ethernet packets as well as the unique packets that are part of the Internet protocol.

Telephone Data Systems

When the wired telephone system converted to digital many years ago, several key data transmission standards were developed. The most common are the T carrier systems, as well as frame relay and asynchronous transfer mode (ATM). The most widely used digital telephone networking standard is the T-1 system. It was developed to transmit 24 digitized telephone lines over a single cable. The voice signals were digitized into 8-bit chunks and then transmitted sequentially over a T-1 line from one central office to another. The basic T-1 frame format is shown in Figure 9.9. It consists of 192 data bits made up of 24 bytes representing individual chunks of telephone calls. An additional synchronizing bit is added. The result is a T-1 signal that transmits at a rate of 1.544 Mbps. And while T-1 is still widely used for digital telephone calls, it is also used for broadband computer data connections and cell phone backhaul.

There are other T carrier systems that are used to multiplex T-1 lines onto larger cables. The most common is the T-3, which allows dozens of T-1 lines to be multiplexed on a single cable at a 44.736-Mbps data rate.

Frame relay transmits data mostly in telephone systems. Both the T carrier and frame relay are synchronous systems, meaning that they are synchronized to a master clock signal.

Asynchronous transfer mode (ATM), as its name implies, is an asynchronous system that transmits data in packets. Each packet is made up of 53 bytes—5 bytes for a header that designates the destination and a 48-byte payload segment. Packets may be digital voice or computer data.

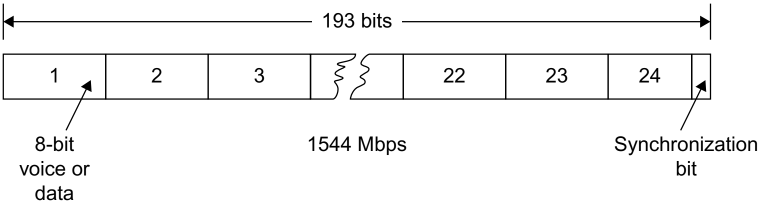

FIGURE 9.9 A T-1 data frame commonly used in digital telephone systems as well as data interconnections in networks.

Optical Transport Network

The optical transport network (OTN) is a technology used to implement the Internet backbone network. This is the core long haul fiber optical network that connects the world together. OTN uses special polarization and modulation techniques to transmit data rates of 40-Gbps and 100-Gbps.

HOW THE INTERNET WORKS

The Internet is an enormous WAN covering the entire world. It consists of many super-fast, fiber optic cable links that are generally referred to as the backbone of

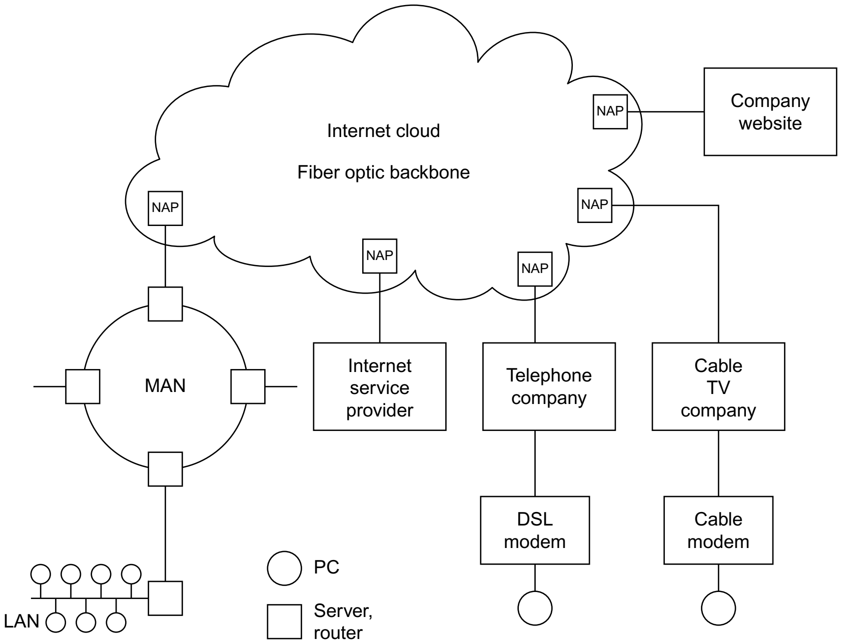

FIGURE 9.10 Internet illustrated as cloud of fiber backbone connections through network access points (NAP) that attach to WANs, MANs, and LANs.

the network. These high-speed links are owned by companies and governments and provide connection points for companies, governments, WANs, Internet service providers, and hosts for websites. These connection points are known as network access points (NAPs). See Figure 9.10. There are dozens of NAPs in the United States and they provide the link to the backbone connections. These backbone connections are worldwide. Because they are complex and interlinked, they are often referred to as the Internet cloud. Since data being transmitted from one point to the other can go by multiple paths in the backbone, there is no way to know the exact path, so the cloud designation is appropriate. You put the data transmission into one NAP entry point to the cloud and it comes out in another. From there it goes to other MANs and LANs for connections to other networks and to individual users.

Data is transmitted over the Internet using a standardized method referred to as TCP/IP. This means transmission control protocol/Internet protocol. Both are protocols for building packets that are transmitted over the Internet.

Assume that a LAN and MAN using Ethernet want to transmit information over the Internet. The Ethernet packets are then sent to a NAP where they are assembled into the packets that actually get transmitted over the fiber optic cable. The TCP assembles the data to be transmitted into unique packets and attaches a header to it, giving the source and destination addresses, a sequence

number, and some error detection and correction information. The general format is shown in Figure 9.11A.

The TCP packets then become the data that is assembled further into Internet packets (see Figure 9.11B). The Internet protocol attaches a header giving source and destination addresses as well as other information about where and how the data is to be sent.

The IP header contains a 32-bit destination address identifying the location of the computer receiving the data. This 32-bit address is divided into four 8-bit segments. Each 8-bit segment is usually referred to by its binary equivalent. The result is the IP address. Every computer and most other devices have an IP address assigned by an organization set up for assigning and managing Internet addresses. You may have seen the address referred to in the format 51.78.23.189. This is called the *dotted decimal format*.

With a 32-bit address, over 4 billion individual computers and other devices can be assigned a unique address. However, we are already beginning to run out of addresses and a new updated form of Internet protocol called IPv6 (Internet Protocol version 6) is gradually replacing it. It has a 128-bit address that provides billions and trillions of additional addresses so that even the smallest inconsequential device can have its own Internet address.

As the data is transmitted over the Internet, it passes through many devices referred to as *routers*. The router is the basic transmission control device of the Internet. What the router does is examine all of the packets transmitted to it and specifically looks at their IP destination addresses. The router temporarily will store data being transmitted and then decide which part of the network it should be connected to next to reach its desired destination. Routers store sets of information called *routing tables* that help the router decide the best transmission path through the Internet.

The data being transmitted ultimately reaches the NAP connected to the network where the destination exists. This may be a company, MAN, or LAN, or it could be an Internet service provider, such as the telephone company or cable TV company that will ultimately connect to the source computer. The source computer then strips away the TCP/IP headers to recover the original Sonet or Ethernet data.

WIRELESS NETWORKS

Wireless networks are usually LANs or PANs, but may also be MANs. Most wireless networks are short-range wireless connections that bring greater mobility as well as freedom from interconnecting cables to networking. Figure 9.12 shows a graph designating the various types of wireless networking schemes in use today. In this graph, each networking technology is defined in terms of its data rate as well as its range. In this section, we take a look at all of these technologies, most of which you have heard of or already use on a regular basis.

Wi-Fi

The most widely used wireless networking technology is referred to by its trade name Wi-Fi, meaning *wireless fidelity*. This the name given to the IEEE's

wireless Ethernet standard designated as 802.11. Wi-Fi was originally developed as a wireless extension to normal Ethernet LANs. It allowed laptops and personal computers and even cell phones to connect to a company or organizational LAN wirelessly instead of the normal CAT5 connection. This not only simplified and in many case eliminated new wiring but also gave employees greater freedom and mobility, particularly since most employees use laptop computers rather than fixed PCs.

Figure 9.13 shows how Wi-Fi works. Each PC, laptop, or cell phone has a built-in data transceiver and antenna that communicate with a wireless access point (AP). This wireless access point is a transceiver that connects directly to an Ethernet switch, which, in turn, connects to the LAN wiring and its server. Access points are placed at strategic locations within buildings to allow as many people as possible to connect wirelessly.

There are also public access points known as *hot spots*. These are present in coffee shops, airports, hotels, and in many other locations, allowing anyone with a laptop or cell phone to connect. These hot spots talk back to a central point by a backhaul method, such as a T1 telephone line or microwave relay link that connects to an Internet service provider that, in turn, is connected to the Internet.

The 802.11 standard exists in several basic forms. The most popular version of this standard is 802.11b. It operates in the 2.4- to 2.483-GHz unlicensed band. It uses the direct sequence spread spectrum (DSSS) and is capable of data rates up to 11 Mbps in a range of up to 100 meters. This frequency band is divided into 11 channels, each 22 MHz wide. The computer and access point decide on which channel to use to minimize interference with other transmissions. If you are close enough to the access point, you can actually get the 11-Mbps data rate, but if you are not, the system automatically ratchets down to 5.5, 2, or even 1 bps depending on the range, interference, and noise or other environmental conditions.

Another popular version of the standard is 802.11g. It is a faster version of Wi-Fi that also operates in the 2.4-GHz band. It can achieve data rates as high as 54 Mbps up to 100 meters. It uses OFDM with 52 subcarriers. The most recent standard is 802.11n, which uses OFDM and MIMO to achieve even higher data rates up to approximately 600 Mbps. Another less popular version is 802.11a, which uses the 5-GHz unlicensed band. It too uses OFDM and can achieve data rates to 54 Mbps. The IEEE is also currently working on an advanced wireless standard that should ultimately be able to achieve a 1-Gbps data rate in the near future.

Wi-Fi is also built into most of the new smartphones. While a smartphone has data capability because of its 3G digital technology, Wi-Fi gives it one more way to access the Internet and email.

Wi-Fi is also the most popular home networking technology. With no wires to install, it is easy to set up and use with a broadband DSL connection or cable TV access.

Bluetooth

Bluetooth was developed as a personal area network (PAN) for connecting computers, cell phones, and other devices up to a range of about 30 feet. It is a low-speed data transmission method. Bluetooth operates in the same 2.4- to 2.483-GHz unlicensed spectrum as Wi-Fi. It uses a technique known as frequency hopping spread spectrum (FHSS), where the data is divided into chunks and transmitted via a carrier that hops from one random frequency to another. Data is transmitted at a 1-Mbps rate using FSK. An enhanced data rate (EDR) version of Bluetooth is also available to transmit at higher speeds up to 3 Mbps. Even newer versions can give data rates as high as 24 Mbps and even higher rates are possible in future versions of the standard. The standard is managed by the Bluetooth Special Interest Group (SIG).

One of the basic features of Bluetooth is that it is capable of forming small networks called piconets. It does this by linking two Bluetooth devices together. One serves as a master controller and it can connect to seven other Bluetooth slave devices. Once the PAN has been set up, the various connected devices can exchange information with one another through the master.

By far the most common application for Bluetooth is cordless headsets for cell phones. But you will also encounter it in some wireless connections between laptops and cell phones. It is also used in some computer peripheral devices such as PC-to-printer connections.

ZigBee

ZigBee is another short-range PAN network technology with the IEEE designation 802.15.4. It uses low power, so the range is typically 100 meters or less, basically depending on the antennas and the physical environment where it is used. ZigBee also operates in that unlicensed spectrum from 2.4 to 2.483 GHz.

The IEEE 802.15.4 standard defines the basic radio technology. It uses direct-frequency spread spectrum (DSSS) and a version of QPSK that gives a data rate of 250 Kbps. The frequency spectrum is divided into 16 1-MHz channels.

The basic function for ZigBee is monitoring and control. Monitoring refers to telemetry that allows sensors to collect information, which is then transmitted by radio to some central collection point. It also allows for remote control of the devices such as lights, motors, and other items. The ZigBee Alliance, the organization that promotes and enhances this wireless technology, has developed a series of applications for industrial monitoring and control, home monitoring and control, energy monitoring (automatic meter reading) and control, and several others.

A major feature of the ZigBee technology is its ability to perform mesh networks. While a typical ZigBee radio node may only have a range of 30 meters or less, the range can be extended by simply transmitting data from one node to another in a mesh network that may cover hundreds of meters, or in some cases even miles. A mesh is shown in Figure 9.14. Each circuit is a ZigBee transceiver node and each line is a wireless path. Mesh networks have many different paths for data and, therefore, are extremely reliable. If one path is blocked or disabled, data can usually find its way to the desired destination by way of another path. For example, in Figure 9.14, a direct path may be from A-D-F-I-K, but if the D-to-F link is blocked or the I node is disabled, the mesh would automatically reroute the data through another path such as A-D-G-J-K.

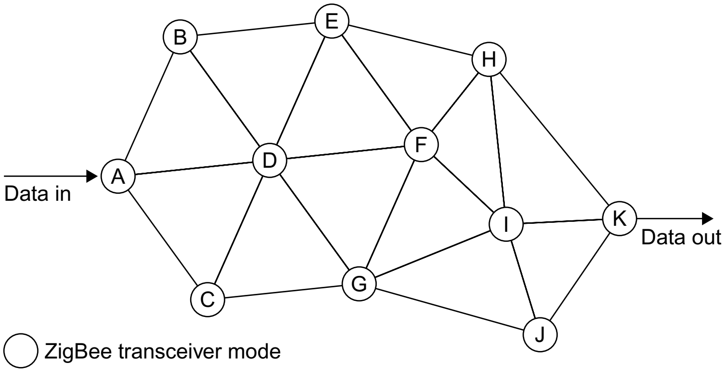

FIGURE 9.14 A mesh network can extend the overall range of a node and provide greater reliability through multiple possible paths. Most wireless mesh networks are ZigBee, but other wireless technologies may be used (e.g., Wi-Fi).

A forthcoming application of the 802.15.4 standard is the replacement of the current infrared (IR) TV remote controls. An RF version called RF4CE is gradually expected to replace IR remotes in all consumer electronic equipment providing longer range and no line of sight limitations. Two-way communications are expected to be implemented.

Ultra Wideband

Ultra wideband (UWB) technology is a very broadband, high-speed PAN designed for transmitting audio, video, and high-speed data. It uses OFDM in the frequency spectrum from 3.1 GHz to roughly 5 GHz. Higher frequencies up to 10.6 GHz are available but not widely used. Ultra wideband has a maximum data rate of 480 Mbps, but the actual rate depends on the range between nodes.

WiMAX

WiMAX is actually a wireless MAN. It was initially designed to offer a wireless alternative to Internet connections to homes, usually by way of cable TV systems or DSL lines of a telephone company. WiMAX is also standardized by the IEEE as 802.16. It comes in two variations, fixed and mobile. The fixed version is used for Internet connectivity in a fixed mode where the nodes in a star-like network are essentially in one position. WiMAX services are now available through an organization such as Clearwire in the United States with base stations with a range of several miles. Laptop computers containing WiMAX transceivers can connect to the network. Data rates will vary depending on the service offered by the company but can be from 1 Mbps to 10 Mbps or more. The technology uses OFDM with modulation schemes including BPSK, QPSK, 16-QAM, and 64-QAM. MIMO may or may not be used.

A mobile version of WiMAX is also available. It is designed for connectivity where laptops and other mobile devices can connect to access points or base stations even while in motion.

Most WiMAX activity takes place in the United States in the 2.5-GHz frequency range and the 3.5-GHz range in Europe, Canada, and Asia. It is expected that WiMAX will be used in the new 700-MHz band for high-speed Internet access.

Radio Frequency Identification and Near-Field Communications

Radio frequency identification (RFID) is a very short-range technology that is intended to substitute for standard bar codes. Practically everything has a printed bar code on it today so that with optical scanners the device can be recognized by a particular part number or other information that identifies it. The bar code readers are normally attached to a computer and, in turn, a network.

RFID devices are small thin plastic tags containing a radio chip that can be read by a wireless reader. The RFID chip contains an EEPROM memory in which is stored the device's unique identification number and other related information. A key characteristic of the RFID tag is that it contains no power source such as a battery. Yet it is designed to transmit its digital code to some external reading device whenever it is interrogated. Figure 9.15 shows how it works.

The interrogation takes place when an external reader made up of a transmitter (TX) sends a radio frequency (RF) signal to the nearby tag. The radio frequency energy received by the tag's antenna is then rectified and filtered into a DC voltage that is used to power up the memory and the modulator circuit that sends data back to the reader. The reader also contains a receiver (RX) that picks up the small signal from the tag and sends it on to a computer where identification takes place.

RFID tags are generally used for what is known as asset tracking. RFID tags are attached to any relatively expensive item whose position is to be monitored, tracked, or otherwise controlled. It is good for keeping track of capital equipment, baggage, manufacturing tools, and other items. It is also used for personnel security on badges that employees wear and is good for animal tracking. One of the most widely used applications is automatic toll collection on highways.

RFID tags come in a variety of sizes, shapes, and technologies. Some of the older tags work at a frequency of 125 kHz or 13.56 MHz. The newer tags work at UHF frequencies in the 902- to 928-MHz range. All of these tags are passive devices with no power other than that received from the reader. Some longer-range RFID tags with small batteries have also been developed.

The unique code stored in the EEPROM is stored during the tag's manufacture. It is then clocked out at a relatively slow rate of speed around 70 kbps. The serial binary data is used in a form of amplitude modulation called backscatter modulation that produces minor variations in the reader's signal that can be converted back into a binary code.

Another similar RFID-like technology is known as near-field communications (NFC). It has an even shorter range of only about 1 foot. It operates on 13.56 MHz. It is mainly designed to be used in credit cards and in cell phones to produce automatic transactions such as credit card purchases or payment for transportation (e.g., train, subway, bus) or access to some facility.

BROADBAND TECHNOLOGY

Whenever you hear the term "broadband," it generally refers to a high-speed interconnection or Internet access. Most broadband systems provide data rates from roughly 1 Mbps or less to well over 10 Mbps, depending on the level of service purchased. Such broadband services are usually provided by cable TV companies or telephone carriers. Other smaller organizations also offer various other types of Internet connectivity.

Cable TV Connectivity

Most cable TV companies offer high-speed Internet connectivity services. What they do is allocate one or more of the 6-MHz wide channels on the cable to this service. (See Chapter 11 on TV.) By using QPSK, 16-QAM, or 64-QAM, a wide range of customers can be offered multiple levels of Internet connectivity service. The customer gets a cable TV modem that connects to the cable along with the TV set. This modem provides the connectivity to a computer via Ethernet. A Wi-Fi access point is often connected to the cable modem to provide wireless connections to the Internet for PCs and laptops.

Digital Subscriber Lines

Digital subscriber lines (DSLs) are high-speed Internet connections that use standard telephone lines. DSL uses the standard twisted-pair telephone lines that come into every home for normal telephone service. These lines, because they were developed only for voice signals, are restricted in bandwidth and data rate. However, special techniques have been developed to allow very high-speed data transmissions on them. DSLs, also referred to as *asymmetric digital subscriber lines* (ADSL), use a variation of OFDM called *discrete multitone* (DMT). What it does is divide the restricted bandwidth of the twisted-pair cable into multiple OFDM channels, each 4 kHz wide. Then the data to be transmitted is divided into parallel paths and modulated using some form of QAM. All of this is handled by a DSL modem connected to subscribers' computers and the home telephone lines.

The speed potential of an ADSL line depends on how far away the subscriber is from the central office. The greater the distance, the lower the data rate. For even the longest runs from 12,000 to 18,000 feet, data rates of up to about 2 Mbps are possible.

Newer versions of ADSL have also been developed to permit data rates of up to about 12 Mbps at a range of 8000 feet and 20 Mbps at a range of about 4000 feet. A newer version referred to as video DSL or VDSL extends the bandwidth further and uses higher-level versions of QAM to get data rates of up to 52 Mbps.

Wireless Broadband

Wireless broadband services are only beginning to become available. A relatively new WiMAX wireless network known as XOHM is offered by Clearwire, a spinoff of Sprint Nextel. It provides fixed wireless data services with data rates in the 1- to 3-Mbps range. WiMAX modems are connected to computers that access nearby base stations within several miles of one another.

The beauty of wireless broadband is that no cables or other hard connectivity is required. These are easy to set up, although at microwave frequencies, range is a problem as are multipath problems with buildings, trees, and other obstructions. However, with high enough antennas and sufficient power, wireless broadband has proved to be practical. It is growing rapidly, particularly in those areas where DSL and cable TV services are not currently available. This is particularly true in rural areas and in some small towns and communities.

Don't forget that wireless Internet connectivity can also be achieved by using the regular cell phone networks. You can purchase a data modem that plugs into your laptop USB connector on a PC. This modem connects you just as it would a cell phone to your cellular network. From there you can use the 3G data service to connect to the Internet, access email, or perform other networking operations.

ISM-BAND RADIOS

The industrial-scientific-medical (ISM) band has been mentioned before. This comprises a group of frequencies or bands set aside for unlicensed data transmission over short ranges. The main application is telemetry monitoring and remote control. The U.S. frequencies are 13.56 MHz, 315 MHz, 433 MHz, and 902 to 928 MHz, with 915 MHz the most common. In Europe, 868 MHz is an unlicensed frequency. Transmitters and receivers are tiny single ICs with power levels from about 1 mW to 1 watt. Modulation is usually ASK/OOK or FSK. Data rates are low from a few kbps to usually no more than 100 kbps.

Some typical applications are garage door openers, remote keyless entry for vehicles, remote thermometers, medical telemetry, remote-controlled toy cars and boats, and sensor reading in industrial applications. Range is no more than a hundred feet or so, but longer ranges to several miles can be achieved with higher antennas.

Chapter 10

Audio Electronics

Digital Voice and Music Dominate

In this Chapter:

- Sound and the electronics that deliver it.
- Digital audio.
- The compact disc (CD).
- Voice and music electronics.

INTRODUCTION

While the telephone, telegraph, and radio are generally considered the first real electronic applications, audio was certainly next. By "audio," I mean sound: voice and music, things we can hear. Audio signals have frequencies within the range of the human ear. Over the years many electronic devices have been developed to amplify, capture, and reproduce sounds of all types. Today, like everything else in electronics, audio electronics is predominantly digital, although many analog devices and systems are still in use. This chapter is a summary of audio devices you know and use every day from stereo systems to iPods.

THE NATURE OF SOUND

Sound is just pressure waves in the air that your ear can hear. Anything that produces a noise or other disturbance produces pressure waves that travel to your ears where the sound waves are converted into signals that your brain recognizes as sound. The frequency range of these air vibrations is 20 Hz to 20 kHz. Our ears do not respond to lower or higher frequencies even though they may be present. Human hearing also varies widely due to age and health status. Age brings on hearing loss, especially of the higher frequencies.

There are four key things needed in audio electronics:

- The ability to convert sound waves into electrical signals.
- The means to convert the electrical signals into sound.

- A way to amplify the signals.
- Media to store or record the signals.

This is what audio electronics is all about.

Microphones

The microphone is the transducer that converts sound waves into an analog signal. The sound waves impinge on the microphone and it causes vibrations that are translated into a signal by either capacitive element or an inductive coil. A technical discussion about microphones is way beyond the scope of this book. In any case, the resulting signal is usually very small, in the millivolt range or even microvolt range. Therefore, it must usually be amplified before it is useful. This is the function of a small-signal amplifier usually called a *preamplifier*. What you do with the signal after that is up to you. Typically it will be amplified further for use in a public address (PA) or other sound system. Or alternately, the voice may be recorded. Many voice signals will be used in a telephone, cordless or cellular.

Speakers

A speaker is a transducer that converts the audio signal into sound waves that you can hear. You have obviously seen a speaker, so little explanation is needed. Its main element is a paper or plastic cone that vibrates at the audio frequencies applied to it. Then it produces the sound pressure waves that our ears will hear.

Figure 10.1 shows how a speaker works. The cone is attached to a form around which a coil of wire is wound. This is the so-called *voice coil*. That voice coil is positioned inside a strong permanent magnet with north and

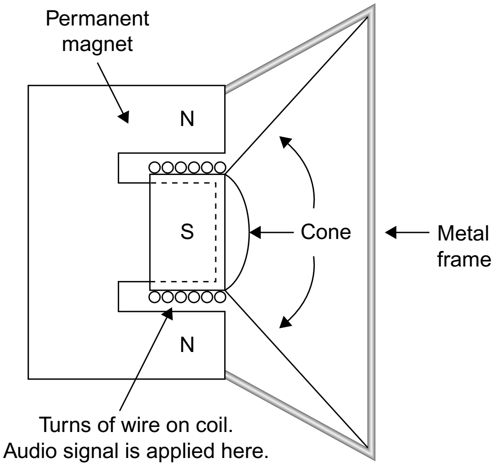

FIGURE 10.1 Cross-section of speaker showing major components and how it works.

south poles. Now when you apply the audio signal to the coil, current flows and causes the coil to become an electromagnet. The electromagnet generates alternating north and south poles as the voice or music signal occurs. These magnetic fields interact with the permanent magnet, causing attraction and repulsion of the voice coil, and the cone moves. The motion of the cone accurately reproduces the original sound waves.

Speakers come in a wide range of sizes and types. Cone speakers are usually called mid-range speakers in that they can reproduce most of the frequency range except for the very low and very high frequencies. Special speakers are used for those frequencies. A woofer or subwoofer is a larger speaker designed for frequencies of about 600 Hz and below. A tweeter is a special speaker optimized for the higher frequencies above 10 kHz. Special filters called *crossover networks* separate the signal into low, mid-, and high frequencies as shown in Figure 10.2.

The remainder of this chapter addresses the amplification and recording or storage of audio signals. Along the way, most analog audio signals are digitized. And many are also compressed to save storage space or reduce the binary data rate for transmission.

DIGITAL AUDIO

The sounds we hear and the sounds we generate are analog signals. A microphone picks up the voice and music and produces an analog signal to be amplified or stored. We have amplifiers and speakers that will accurately reproduce the

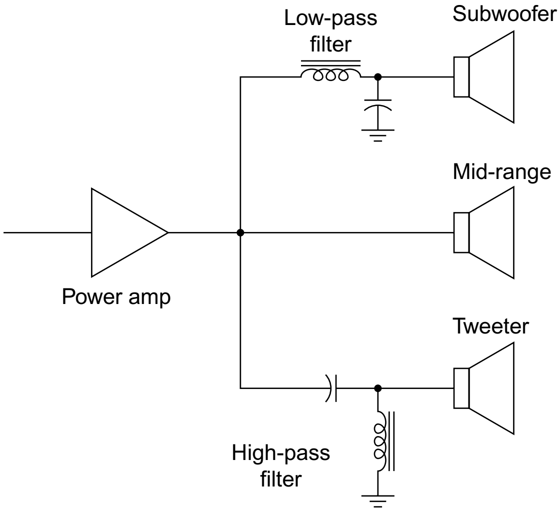

FIGURE 10.2 Cross-over networks keep signals of different frequencies separate for appropriate speakers.

sounds. But the real challenge with audio is capturing, storing, or recording the sounds for later reproduction. With today's digital techniques, we can store not only voice and music more accurately than before, but we can also transmit it more easily by radio, TV, or the Internet.

Past Recording Media

Edison invented the phonograph in the late 1800s. This was the first device ever conceived to record voice. A microphone converted the sound into vibrations that moved a sharp needle in direct accordance with the sound. The needle cut a varying groove in the wax coating on a rotating cylinder. Later, a needle placed in the groove moved the diaphragm in a horn speaker that translated the movement into sound. The quality was poor but it worked, and the concept was soon translated into what we know as a *phonograph record*. The record disc is rotated while a needle cuts a spiral groove into the plastic that accurately captures the sound. To reproduce the sound the disc is rotated at the same speed and a needle is placed in the groove to reproduce the sound in a speaker. A transducer converts the movement of the needle in the groove into an analog signal that is amplified.

Early records spun at a speed of 78 rpm and could only hold a few minutes of sound. Later a smaller 45-rpm record was invented to play minutes of music at a lower cost. Then a larger long-playing record spinning at only 33⅓ rpm was produced that could hold an hour or so of sound. Stereo or two channel sound was also effectively recorded into a V-shaped groove in the record.

Records were soon upstaged by magnetic tape. A plastic such as Mylar was coated with a powdered iron or ferrite magnetic material. The music or sound was then applied to a magnetic coil that put a magnetic pattern on the tape representing the sound. A coil passed near the tape would convert the magnetic pattern variations into a small voltage to recover the sound. Reel-to-reel tape was popular for a while, but magnetic tape became the recording media of choice for years when the Philips cassette tape was invented. Other formats like the ever-popular 8-track unit were also used.

All of these formats worked well but had their limitations. Record grooves wore out with usage causing the high-frequency response to be eroded. Scratches and dirt on the record also produced noise. As for tape, it had good frequency response but had its own noise that could not be reduced below a certain level. The dynamic range of both was poor.

Digital technology has solved all these problems. Now the most popular medium is the compact disc (CD), which records sound in full digital format. It has very low, practically undetectable noise, wide frequency response, and a very long life. The cost is also low.

Digital sound is also routinely stored in computer memories like flash EEPROMs and transmitted over the Internet. With digital techniques, sound can also be processed with DSP such as compression, filtering, and equalization.

Dynamic Range

Dynamic range refers to the difference between the highest and lowest volumes of sound that a system can handle. It is a measure of how wide an amplitude range a particular storage media can record or an audio system can accommodate. It is also a way to state the maximum sound pressures that our ears can withstand and the lowest levels that we can hear.

The upper level of amplitude is set by our ears and the level at which distortion occurs. The lowest levels of the dynamic range are determined by the noise in the system. Noise is the random voltage variation caused by thermal agitation of electronics in electronic components and random variations in the magnetism on a magnetic tape or disc. As the volume of a sound gets lower at some point it will be smaller than any noise present and not distinguishable from the noise background.

In general, the wider the dynamic range the better. It usually means lower noise and greater volume (loudness) to better match the range of human hearing.

Dynamic range can be stated in terms of power or voltage. It is usually a very wide range, so we resort to a unique mathematical method to express it. The term decibel (dB) refers to how dynamic range is presented. In math form you take the ratio of the maximum and minimum voltage, take the logarithm of that, and multiply by 20:

$$\mathrm{dB} = 20\log\left(V_{max}/V_{min}\right)$$

For power,

$$\mathrm{dB} = 10\log\left(P_{max}/P_{min}\right)$$

The dynamic range of a typical phonograph record is probably about 50 dB, and magnetic tape, about 55 dB. But a compact disc (CD) is approximately 90 dB, the best we have.

Dynamic range can be improved by lowering the noise in a system. This can be done with special signal-processing techniques. The most notable are methods produced by Dolby.

Digitizing Sound

Most digital sound and music is digitized with a sampling rate of 44.1 kHz or 48 kHz. Recall the Nyquist requirement that to capture and retain the frequency content accurately, the analog signal has to be sampled at least twice the highest frequency of the sound. Since most music and the human ear cut off at about 20 kHz, then any sampling rate greater than $2 \times 20\,\mathrm{kHz} = 40\,\mathrm{kHz}$ will satisfy that requirement. The rate of 44.1 kHz was standardized for CDs and 48 kHz for professional recordings. At 44.1 kHz, a sample is taken every $1/44{,}100 = 22.676$ microseconds.

Figure 10.3 shows the sampling of an analog signal. The smooth curve is the analog music or voice. At each vertical interval a sample is taken. In this

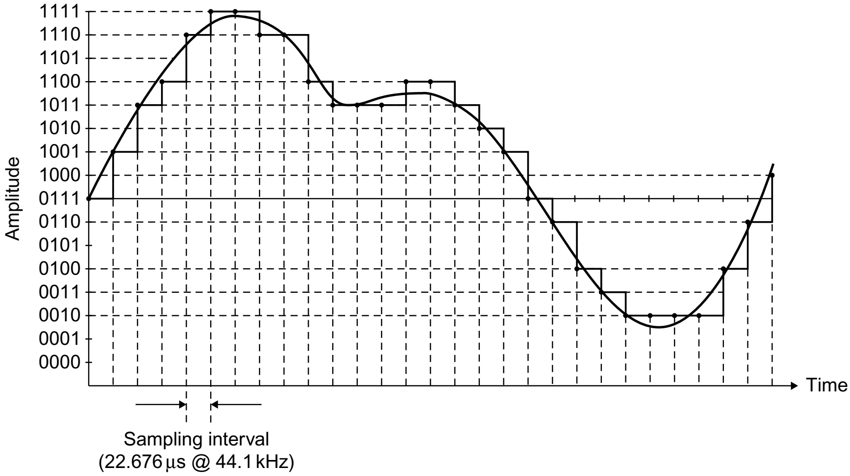

FIGURE 10.3 How audio signal is digitized. In this example, each sample is assigned a 4-bit code. The stepped approximation shown is what a DAC would deliver to the speakers.

example, a 4-bit ADC is used so there are $2^4 = 16$ possible levels. Note the 4-bit code associated with each sample amplitude. The binary samples are stored for later playback. When sent to a DAC, the samples will reproduce the audio in a stepped approximation shown overlaid with the analog signal. Some low-pass filtering of that signal will produce a sound which almost duplicates the original.

Digitizing audio usually results in each sample producing a 16-bit word. With 16 bits you can represent $2^{16} = 65{,}536$ levels. That produces a dynamic range from the highest to lowest amplitude levels of 65,536 to 1. On the decibel (dB) scale, that is a range of 96 dB—far greater than any dynamic range of previous analog recording methods. And noise is virtually nonexistent. It is so low no one can hear it. The overall result is a highly accurate way to capture sound and music. The 16-bit words can then be conveniently stored in a memory, or captured on a compact disc.

Digital Compression

Digital compression is a mathematical technique that greatly reduces the size of a digital word or bitstream so that it may be transmitted faster or stored in a smaller memory. Digitizing sound creates a huge number of bits. Assume stereo music that sampled at a rate of 44.1 kHz to create 16-bit words for each sample. One second of stereo music, then, produces $41{,}000 \times 16 \times 2 = 1{,}411{,}200$ bits. A 3-minute song is $60 \times 3 = 180$ seconds long. The result is $1{,}411{,}200 \times 180 = 254{,}016{,}000$ bits. Since there are 8 bits per byte, the result is 31,742,000 bytes or nearly 32 MB or megabytes. That is an enormous amount of memory for just one song. With a recording medium like the CD with a storage capacity of about 700 MB, that is okay. But for computers or portable music devices, it is impractical, not to mention expensive. And to transmit that over the Internet would take about 4 minutes at a 1 Mb/s rate. Pretty slow by today's standards.

The solution to this storage and transmission problem is to compress the bitstream into fewer bits. This is done by a variety of mathematical algorithms that greatly reduce the number of bits without materially affecting the quality of the sound. The process is called *digital compression*. The music is compressed before it is stored or transmitted. Then it has to be decompressed to hear the original sound.

The two most commonly used music compression algorithms are MP3 and AAC. MP3 is short for MPEG-1 Audio Layer 3, the algorithm developed by the Motion Picture Experts Group as part of a system that compressed video as well as audio. AAC means advanced audio coding. MP3 is by far the most widely used for storing music in MP3 music players and sending music over the Internet. AAC is used in the Apple iPod and iPhone and used on the iTunes site to send music. It is also part of later MPEG2 and MPEG4 video compression formats. Both methods significantly reduce the number of bits to roughly a tenth of their original size, greatly speeding up transmission and easing storage requirements. There are many more compression standards out there, but these are by far the most used and the ones you will most likely encounter.

To perform the compression process you actually need a special CPU or processor. It is typically a special DSP device programmed with the algorithm for either compressing or decompressing the audio.

There are also a number of compression methods used just for voice. Voice compression was created to produce signals for telephony. Most phone systems assume a maximum voice frequency of 4 kHz. The most common digitizing rate is twice that or 8 kHz. Eight-bit samples are typical. If you digitize voice creating a stream of samples in serial format, the signal would look like that in Figure 10.4. Each sample produces an 8-bit word where each bit is $125/8 = 15.625\,\mu s$ long. That translates to a serial data rate of $1/15.625\,\mu s = 64$ kbps. This takes up too much bandwidth in a telephone system, so compression is used. The International Telecommunications Union (ITU), an international standards organization, has created a whole family of compression standards. These are designated as G.711, G.723, G.729, and others. These mathematical algorithms reduce the bit rate for transmission to about 8 kbps. You will see them used in VoIP (voice over Internet phone) digital phones, which are gradually replacing regular old-style analog phones.

There are many other forms of audio compression. Another common one is Dolby Digital or AC-3 that is used in digital movie theater presentations and some DVD players.

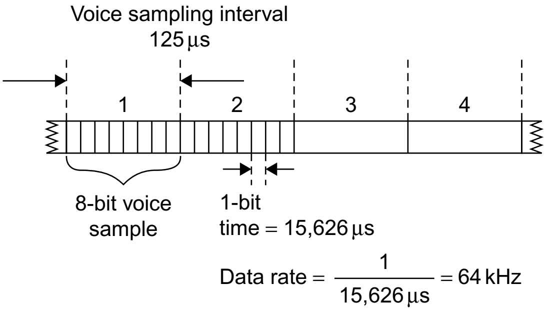

FIGURE 10.4 Voice signals up to 4 kHz for the telephone are sampled at an 8-kHz rate, producing an 8-bit sample, each 125 microseconds. Stringing the samples together in a serial data stream produces a digital signal at a 64-kHz rate.

How an MP3 Player Works

MP3 players such as the Microsoft Zune or Apple iPod are amazing electronic systems in a hand-held package. They all take the general form shown in Figure 10.5. At the heart of the player is a processor. It may be a general processor or a DSP. In some cases, two processors are used, one to control the player buttons, controls, and display, and other general housekeeping functions; a separate DSP handles the compression/decompression. A ROM holds the general control program for the device. A large flash EEPROM is used to store the music in compressed form. Some devices also provide for an external flash memory plug-in device to hold more music. A USB port is the main I/O interface to connect to a PC for the music downloads.

The codec in the device is the coder-decoder. This chip holds the ADC to digitize music from an external source such as a microphone (coder) and the DACs that decode or translate the decompressed audio back into the original analog music for amplification. Class-D switching power amplifiers are used for the headphones to reduce power consumption. One or more internal speakers may also be used. Other circuits include the LCD display and its drivers and LED back-lights if used. A power management chip is normally used to provide multiple DC voltages to the different circuits and to manage power to conserve it. This section also contains the battery charger.

The Compact Disc

The compact disc (CD) is by far the most popular digital audio medium in use today. It has been around since the 1980s and is still going strong. It has virtually totally replaced the Philips cassette magnetic tape cartridges and vinyl phonograph discs. About the only competition the CD has is from flash EEPROM devices such as those used to store MP3/AAC music for portable music players.

FIGURE 10.5 General block diagram of a digital music player like Zune MP3 or Apple iPod.

You have probably seen a CD. Let's add a little background so you will appreciate the CD. It is a 4.72-inch (120-mm) diameter disc made of plastic. It is about 0.05 inch (1.2 mm) thick and has a hole in the center for mounting on the motor that spins the disc. It is actually a sandwich of clear plastic and a thin metal layer for reflecting light.

The music is recorded on the disc in digital format. A laser actually burns *pits* into the plastic representing the 1's and 0's of the digital data (see Figure 10.6). These pits are extremely small, about 0.5 μm wide (a micron designated μm is 1-millionth of a meter). The flat areas between the pits are called *lands*. A binary 1 occurs at a transition from a pit to a land or vice versa while the land is a string of binary 0s. The binary data is recorded as a continuous spiral track about 1.6 μm wide, starting at the center and working outward. That is a very efficient way to store the data, but it means that the motor

speed must vary to ensure a steady bit rate when the music is played back. The pickup mechanism will experience higher speeds at the center of the disc and lower speeds at the outer edges of the disc, so that a speed control mechanism keeps the recovered data rate constant.

The music on a CD is derived from two stereo channels of music with a frequency response from 20 Hz to 20 kHz. Digitization occurs at the standard 44.1-kHz rate. Each sample is 16 bits long. The 16-bit words from the left and right channels are alternated and formatted into a serial data stream that occurs at a rate of 44.1 kHz $\times$ 16 $\times$ 2 $=$ 1.4112 MHz. The 16-bit words are then encoded in a special way. First, they undergo an error detection and correction encoding scheme using what is called *cross-interleaved Reed-Solomon code* (CIRC). This coding helps detect errors in reading the disc caused by dirt, scratches, or other distortion. The CIRC adds extra bits that are used to find the errors and fix them prior to playback.

Next, the serial data string is then processed using what is called eight-to-fourteen modulation (EFM). Each 8-bit piece of data is translated into a 14-bit word by a look-up table. EFM formats the data for the pit-and-land encoding scheme. Finally, the completed data is formatted into frames 588 bits long and occurring at a rate of 4.32 Mbps. That is the speed of the serial data coming from the pickup assembly in a CD player before processing.

To recover the audio from the CD, the disc is put into the player and a motor rotates it. Refer to Figure 10.7. A laser beam is shined on the disc as indicated in Figure 10.6. The reflections from the pits and lands produce an optical light pattern that is picked up by a photodetector that converts the light variations into the 4.32 Mbps bitstream. A motor control system varies the speed of the motor to keep the data rate steady. The data stream goes to a batch of processing circuits. First, the EFM is removed, and then a CIRC decoder identifies and repairs any errors and recovers the original 1.41-Mbps data stream. A demultiplexer separates the left- and right-channel 16-bit words and sends them to the DACs, where the original analog music is recovered and sent to the power amplifiers and speakers.

The CD can store lots of data. Its capacity is in the 650- to 700-MB range. That translates into a maximum of about 74 minutes of audio. And this is not compressed.

AV RECEIVER

An HDTV receiver is usually at the heart of most consumer electronics home entertainment systems. A secondary piece is the AV (audio–video) receiver, which provides the audio component of the entertainment. The systems usually include the CD player, several radio options, and all the audio power amplifiers that operate the multiple speakers. The AV receiver also accepts inputs from the TV set, DVD player, and other external devices to provide higher-quality sound. This section provides a look at this piece of equipment and how it works.

Figure 10.8 shows a general block diagram of the AV receiver. Note the multiple power amplifiers on the right. These drive the speakers that are part of a surround sound system. Most of these are class AB linear amplifiers that deliver power levels from about 20 watts per channel to over 100 watts in the larger units. The frequency response is 20 Hz to 20 kHz or more with a distortion level of 0.5 to 0.9% or less.

The power amplifiers get their inputs from multiple sources. These sources include audio from the internal radio receivers and the CD player as well as many other external sources. These sources include the TV receiver, DVD player, VCR, and a cable or satellite box, as well as audio from older devices like tape players and phonographs. Many receivers also accept inputs from an iPod or other MP3 music player. A large switching matrix is used to select the

Radio Choices

All AV receivers contain the traditional AM and FM analog radios. These are still popular sources of music. But more and more the most recent receivers contain one or more digital radio sources such as HD radio or satellite radio.

HD radio is becoming more popular each year. This is a digital radio broadcast option available at most U.S. radio stations today. The AM and FM sources are digitized and broadcast on the same frequencies but with digital modulation techniques (OFDMs). The result is an improvement in the signal. Digital signals offer slightly better frequency response on both AM and FM. AM signals will sound more like FM and FM signals will be nearly CD quality. Furthermore, the digital signals are more noise- and fade-free than the standard AM and FM signals. While HD radio was first made available in automobiles, it is now widely available for home use. Separate HD radios can be purchased at most consumer electronics stores. And more HD radios are being built into AV receivers.

Satellite radio was also first made popular in automobiles. Yet separate home receivers are available. Some AV receivers now include satellite radio capability. Satellite radio has been available from two sources, Sirius Radio and XM Radio. Both are subscription services with hundreds of radio, music, news, sports, and other channels. The signals are digital, delivering near CD-quality sound. Both systems use the 2.3-GHz microwave band. The main difficulty when using satellite radio at home is that an outside antenna is needed. Some radios supply a small antenna for window mounting so that the antenna can "see" the satellites in the sky. Otherwise, poor or no reception may occur.

Surround Sound

Virtually all audio sound today is stereo. That is, the music comes from at least two speakers, one on the left and one on the right. The sound is recorded as two separate channels with different microphones to provide a stereophonic experience to the listener. A minimal system uses two speakers but some add a subwoofer for good bass reproduction. This is sometimes referred to as a 2.1 stereo system, that is, two speakers and one subwoofer.

New audio systems offer surround sound. These systems feature six, seven, or eight speakers. The idea is to totally envelop the listener with sound as it might be heard in a concert hall or theater. There are speakers in front and at the rear. The first surround-sound implementations were analog but today most surround sound is fully digital. The most common surround-sound method is Dolby Digital 5.1, which uses five speakers and a subwoofer as shown in Figure 10.9. These are left front (LF), right front (RF), center (C), left rear (LR), and right rear (RR). Then there is one subwoofer. The woofer can be positioned

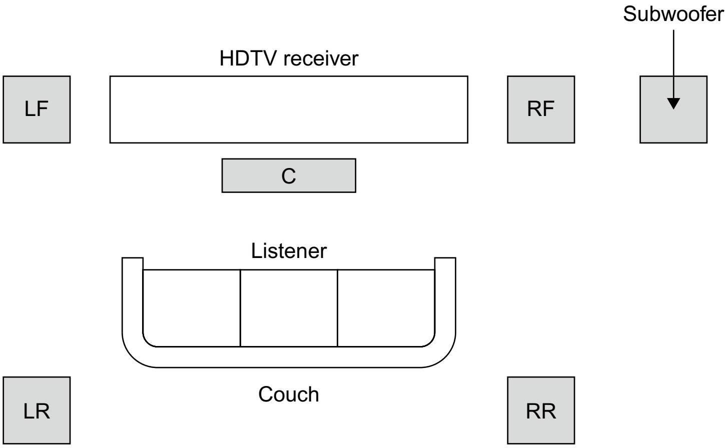

FIGURE 10.9 How 5.1 surround sound system is set up.

anywhere but is usually at the front. Each speaker is driven by its own amplifier in the AV receiver.

The big question that you may have is where do the six channels of sound come from? Not from the radio or a CD for sure, both of which are stereo only. In most cases, the sound signals will come from a DVD player. Right now it is about the only common source of 5.1 surround sound, although some HDTV programs support it. During recording of the original material, one microphone is used for each channel. The digitized audio for each of the channels is stored on the DVD.

Incidentally, there are more elaborate versions of surround sound. For example, 7.1 adds two more speakers on the left and right. As of now there are few, if any, 7.1 music sources available.

When you play the DVD, the digital signals from each channel are sent to a special chip that decodes them and otherwise performs necessary noise reduction, equalization, and other operations. The recovered signals are then sent to DACs for conversion to their original analog format for amplification.

SPECIAL SOUND APPLICATIONS

When you think of audio or sound, you think mainly of voice or music reproduction. Yet, electronic sound is used in lots of additional places. Some interesting examples are in musical instruments, sonar, ultrasound, and hearing aids.

Musical Instruments

Musical instruments produce their own sounds, of course. Each has its own unique signature made up of the basic notes or tones to which are added the mix of harmonics or overtones unique to the physical structure of the instrument. Some instruments like horns and drums rarely need amplification. Other instruments like guitars and violins commonly need some amplification, especially in large venues such as on stage addressing hundreds or thousands of people. Special microphone-like devices called pickups are used with string instruments. The pickup is usually one that converts the string vibrations into a small signal that is then amplified.

One of the most popular electronic instruments is the *synthesizer*. It has a keyboard like a piano. The keys are equivalent to those on a piano. Each key then triggers the electronics to generate a tone of the desired frequency. That tone is especially modified by DSP circuits to sound like that note played on a piano, an organ, or any other musical instrument. The DSP synthesizes or constructs the tones digitally and sends them to a DAC that converts them into the analog sound to be amplified.

Are Vacuum-Tube Amplifiers the Best Audio Amplifiers?

Vacuum tubes? I'm kidding, right? Actually, no. There are many audio experts, especially guitar players and some recording studio engineers, who still believe that vacuum-tube amplifiers are superior to solid-state amplifiers. And as it turns out, the largest market for general vacuum tubes today is guitar, high-end stereo, and recording studio amplifiers.

Contrary to popular belief, vacuum tubes did not really go away when transistors and integrated circuits came along. They are still widely used in China, Russia, and a few other countries. And that is where most tubes are made these days. Vacuum tubes are still widely used. Cathode ray tubes (CRTs) or picture tubes are still at the heart of many TV sets and computer video monitors. Magnetrons are vacuum tubes that are in every microwave oven. And microwave vacuum tubes, such as traveling-wave tubes (TWTs) and klystrons, are still used in high-power microwave transmitters. And vacuum-tube audio amplifiers.

Why are vacuum-tube amplifiers so popular still? It is the unique sound they produce. It is a sound that musicians appreciate and want in their sound mix. And the sound is difficult and expensive to reproduce in a solid-state amplifier. The sound is smoother and less harsh. The sound is "warmer," and the compression that such amplifiers produce when overloaded is exactly what makes rock and country music sound like it does. It looks like vacuum tubes will be around much longer, but prices are sky high and some tube models are hard to find.

Noise-Canceling Earphones

You have probably heard of these or maybe seen or used them. They make clever use of analog signal processing to greatly minimize surrounding noise when you are trying to listen to music with headphones.

First, most of these headphones try to isolate the actual headphone from the surroundings with a tight-fitting ear bud or soft foam pads around the earphone that limit the amount of external noise getting to your eardrum. This is called *passive noise control*.

Second, each earphone contains a built-in microphone that picks up the surrounding noise. It amplifies it then inverts it in phase. The original noise from the microphone is then added to the inverted noise. Being the same but exactly out of phase with one another, the two noise signals cancel one another. The cancellation is not perfect, but the noise reduction is significant. It can greatly minimize noise on a plane or in a car or other types of noisy environments.

Sonar

Sonar means sound navigation and ranging. It is basically the underwater equivalent of radar. It is used on ships and submarines for making depth measurements, detecting underwater objects, and for warfare. The two types of sonar are passive and active.

Passive sonar is simply the idea of putting underwater microphones called *hydrophones* on a long wire or arrays of such microphones in the water to listen for any sounds that occur. Amplifiers boost the signal levels and various filters help sift through all the complex signals that can be heard. In military applications, the sounds are digitized and various DSP programs help filter and identify specific sounds. Many ships create unique sounds called signatures that can be digitized and stored for comparison to any sounds picked up for positive identification. The sounds include fish and other sea life, boat and ship engines, motion through the water by a ship or boat, or any noise that occurs inside a submarine. Sound travels very easily through water so is easy to pick up. With practice and experience, a sonar operator can identify almost everything occurring over a wide range around the microphone array.

The other form of sonar is *active*. This is like radar where a high-frequency pulse of sound is applied to a transducer to convert the pulse into sound waves for transmission through the water. The frequency of the pulse is usually ultrasonic, that is, above most human hearing. Frequencies from about 15 kHz to 1 MHz are used, depending on the application. The pulse of sound travels out from the transducer and is then reflected off distant objects. The reflections go back to the source where they are picked up by a microphone. Then, knowing the speed of sound transmission in water, the distance to the object can be computed. Sonar depth sounders point the transducer downward to get a measure of the distance to the bottom. Sonars can easily pick up reflections from ships miles away for navigation safety purposes or for military actions.

Hearing Aids

Electronic hearing aids have been around a long time. The older analog types were large and cumbersome but worked fine. Integrated circuits made them much smaller and more acceptable to the hearing impaired. Today, the newer hearing aids use digital technology. The microphone picks up the sound and amplifies it then digitizes the sound in an ADC. A DAC can then translate the sound back into audio for amplification and application to the earphone. Most digital hearing aids now incorporate DSP filters. These filters may be customized to the frequency response of the ear, correcting for different frequencies. Mostly the high-frequency response is lost due to aging. Using an external computer, each hearing aid can be adjusted from volume and frequency response to fit the exact deficiency.

Project 10.1

Experience Digital Radio

Digital radio in the United States is available from satellites and via the existing AM and FM analog stations through HD radio. Both offer commercial-free music and other content in multiple channels. HD radio is free but satellite radio is a pay-for-listen service.

In the United States, two satellite radio services were established in the early 2000s, XM Radio and Sirius Radio. Recently the two services merged to form Sirius XM Satellite Radio. Both offer subscription services to music, news, sports, and other information. Both services operate in the 2.3-GHz band, and get their signals from satellites. Special receivers and antennas are required.

Satellite radio is a digital service and both systems used compressed audio for signal transmission. HD radio is simultaneously broadcast with existing AM and FM analog signals. A special receiver is needed to receive it. The digital techniques greatly improve sound quality.

A good project if you are a music lover is to try one or both of these services. You can get an HD or satellite radio for your vehicle or you can buy a home unit. Some high-end AV receivers have one or the other in addition to the traditional AM and FM radios. You can purchase home desktop units from Best Buy and other electronics dealers for a reasonable price.

HD radio is free and you will find that some stations transmit additional digital channels not available in analog form. These give you more music genres. No special antenna is needed.

To learn more about HD radio, do a Bing, Google, or Yahoo! search. And go directly to the company that invented HD radio, iBiquity (www.ibiquity.com), for more details.

You can also buy a satellite radio from several local sources. But you will need to subscribe. Go to www.sirius.com and www.xmradio.com.

INTRODUCTION

Nothing in electronics has affected us more than the development of television. Okay, I haven't forgotten the PC and the Internet, which have also seriously impacted our lives. But TV came first and has been working its magic on us for far longer. The impact of television or video on our lives is significant in that we spend more than half our waking hours in front of a TV screen, either watching TV or working with a video monitor on a computer. The social and political impact has been enormous. And, of course, you also interact with the liquid crystal display (LCD) screens on cell phones, laptops, and personal navigation devices. For this reason it helps to understand a little bit about how video works. Video is perhaps one of the most complex segments of electronics, but this chapter makes those fundamentals easy to understand.

VIDEO FUNDAMENTALS FOR THE IMPATIENT

The main feature of any video device is the screen. The first video or TV screens were cathode ray tubes (CRT) and those are still used in older TV sets and computer monitors. The most commonly used TV and video screen today is the LCD. LCD screens are used in the newer TV sets and in most personal computers.

They are also used in laptops, netbooks, cell phones, personal navigation devices, and anything else that has a screen on it. TV sets also use plasma, digital light-processing (DLP) projection technology, and other methods to display very large pictures. There is more detail on TV screens later in this chapter, but for now, the most important part of understanding video is to learn the methodology used to create and present video regardless of the screen type.

A video system is a method for converting a picture or scene into an electronic signal that can be transmitted by radio or cable or stored electronically. Some type of device is needed to take in the light and color information from a picture or scene and convert it into an electrical signal. Once in electrical form, the video can be modulated onto a radio carrier for transmission or electronically stored. The process of converting the scene or picture into an electrical signal is known as scanning.

Scanning Fundamentals

A video signal is usually generated by a video camera. The camera takes the scene and scans it electronically, dividing it into hundreds or even thousands of very thin horizontal lines (see Figure 11.1).

The horizontal scan lines comprise a sequence of light and color variations. The camera produces an analog signal whose frequency and amplitude vary with the brightness and color changes along the scan line. The whole idea in video is to transmit the video signal one scan line at a time at very high speeds. If you are not transmitting the signal by radio or cable, you can store it, such as recording it on magnetic tape. In any case, the received signals are then converted back into scan lines and applied to the screen by scanning the lines across the receiving screen very fast from left to right and top to bottom.

The secret to producing a high-quality video picture is to use enough scan lines with enough detail in each so that the color, brightness, and fine detail in the picture are retained. Note in Figure 11.1 that the analog signal for one scanned line is such that the higher-amplitude voltages are closer to black while the lower-amplitude signals are closer to the white level. This is what a scan line from a monochrome or black and white (B&W) video system produces. It is called the *brightness* or *Y signal*. Color will be covered later.

Aspect Ratio

When talking about TV screens, the key factors are size and aspect ratio. The *size* is usually the diagonal measure of the screen in inches. The *aspect ratio* is the ratio of the picture width to the picture height. Standard TV sets and video monitors use an aspect ratio of 4:3 as shown in Figure 11.2. Most of the newer TV screens and video monitors have an aspect ratio of 16:9. This wider format was chosen because it is a better fit with the wide-screen movie formats used by Hollywood.

Persistence of Vision

When you think about it, it just doesn't seem possible that a complete picture or scene can be reproduced in electronic format by scanning. The scanning process just breaks the picture or scene down into hundreds or perhaps thousands of scan-line signals, and the only way that a picture can be created is for those scan lines to occur at a very high rate of speed. Luckily, this technique works because we all have a visual characteristic known as persistence of vision. Persistence is that characteristic of the eye which prevents it from following very high-speed changes in light variations. In other words, if the scan lines are traced across the screen at a very high rate of speed, your eye simply cannot follow them one at a time but instead puts the whole thing together and sees a single steady picture. If you scan at too low a rate, you will actually begin to see the scan lines and your eye will interpret this as a kind of flicker.

The concept of persistence of vision has been known for decades. Motion picture films take advantage of this characteristic of our eyes as well. Remember that movies are just a high-speed sequence of individual still pictures recorded on film. If you can get the frame rate up to a level of approximately 24 frames per second or faster, your eye will translate the changes from one still frame to the next as motion.

Analog TV

As you probably know, the Federal Communications Commission eliminated analog TV broadcasts in the United States as of June 12, 2009. But while analog TV has been replaced by digital TV, that doesn't mean that it isn't still around. You will still find analog TV in many other countries of the world, and it is also still widely used in closed-circuit television. In any case, it is such a widely used standard that understanding it is useful.

Back in the late 1940s and early 1950s, the United States created what is called the National Television Standards Committee (NTSC) TV standard. It basically specifies that a picture is made up of 525 horizontal scan lines, known as a video *frame*. As it turns out, one frame is actually made up of two fields of 262.5 scan lines. The scene or picture is first scanned 262.5 times from top to bottom, creating one field. This field is then transmitted at a rate of 60 fields per second. Then the scene is scanned again with another 262.5 lines and these are transmitted next. The second field is interlaced with the first field to form the complete 525 line picture. See Figure 11.3. The result is that you will see 30 complete 525-line frames per second. This is fast enough for persistence of vision to work nicely. The interlacing helps significantly in reducing any perceived flicker.

One thing that you may be wondering is how do you keep the TV receiver screen in step with the video camera or other video source? This is solved by creating synchronizing pulses that are transmitted before and after each scan line (see Figure 11.3). After one field is scanned, a larger group of synchronizing pulses occurs between fields to cause the receiver to start the scanning back at

Other World TV Systems

The U.S. NTSC analog system is used in Canada, Mexico, and Japan. But other analog systems are used throughout the world. In Europe, specifically the UK, Germany, Italy, and Spain, the PAL (phase alternation line) standard is used. It uses 625 scan lines with a frame rate of 25 frames per second. In France and in some other countries, a system called SECAM for Sequenteil Couleur a Memorie (or sequential chrominance and memory) is used. It too uses 625 scan lines and a 25-frame-per-second rate. PAL and SECAM systems have a better vertical resolution for picture detail because of the greater number of scan lines, giving a perceptibly improved picture over the NTSC system. Most of the other countries of the world have adopted one of these three systems.

the top again. The synchronizing pulses are transmitted or stored along with the analog video signal for each line. These synchronizing pulses are then used to trigger the receiver's circuitry to make sure that the scene is sequenced properly on the screen.

Digital TV

Most TV and video now is transmitted and stored in digital or binary format. Scanning is still the process used to convert the scene into an electrical signal, in this case a stream of binary numbers representing the brightness and color detail. Each scan line is still essentially an analog signal but that is converted into a sequence of binary numbers by an analog-to-digital converter (ADC). The basic process is illustrated in Figure 11.4. The ADC samples are measures of the analog signal at a constant rate, as shown by the dots along the curve

in Figure 11.4. Remember that in order to retain the information in an analog signal when it is converted into digital, the signal must be sampled at a rate at least twice as fast as the highest-frequency signal contained in the analog signal. Since video signals contain extremely high frequencies, the sampling rate is very fast. Most video contains scene details with frequencies beyond 4 MHz. That means a sampling rate of at least 8 MHz to capture the detail. In any case, each sample results in an 8-bit binary number. These bytes, one representing each of the sequential samples, are sent one after another in a serial binary data stream as shown. The video data can then be transmitted or stored.

Each of the binary numbers produced by sampling produces what we call a *pixel* or picture element. This particular binary number will ultimately translate to a specific analog voltage value and produce a specific brightness level along the scan line.

One way to visualize a digital video display is to think of it as an array, or horizontal scan lines, each made up of a sequence of pixels (see Figure 11.5). Each pixel is a dot of light or, in this case, a square. That pixel is derived from a specific binary number developed during the scanning and sampling process. Each of those pixels represents a specific brightness level from white to black. A digital-to-analog converter (DAC) converts the binary brightness value back into a specific shade of gray.

Digital TV (DTV) uses the interlaced scanning principles described earlier to help minimize flicker. But it also uses a faster progressive scan. This is where each scan line making up the screen is scanned sequentially one after the other from top to bottom. To minimize flicker, *progressive scanning* must be done at a higher rate of speed than interlace scanning. Progressive scanning

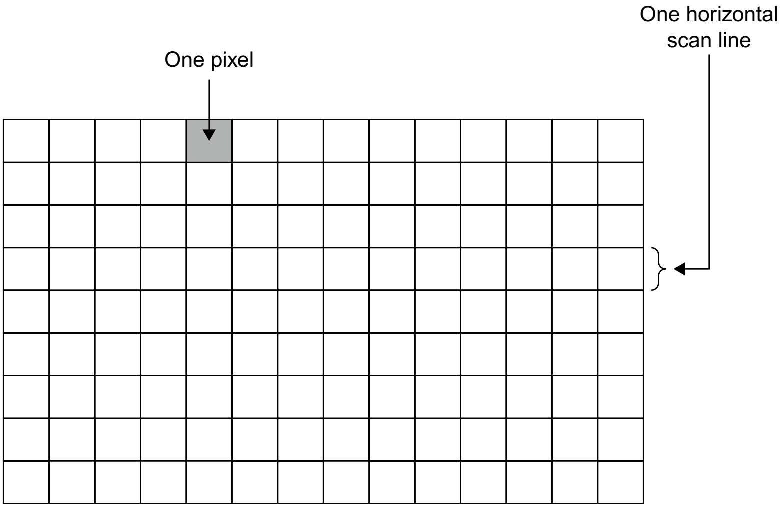

FIGURE 11.5 TV screens can be thought of as thousands of rows and columns of pixels, each represented by data.

is used simply because it creates a sequence of digital numbers that is more conveniently stored and processed one after the other than in a two-step interlaced process.

DTV uses a variety of different formats. In the basic format, it produces 480 scan lines with 640 pixels per line. This is roughly the equivalent of what you would see with an analog TV signal. This is what we call the DTV standard-resolution format. Both interlaced and progressive scanning formats can be used with rates of 24, 30, and 60 frames per second.

Picture Resolution

One thing that you should understand about video is the concept of resolution. This refers to how much fine detail you can see on the screen. In analog TV, brightness and color detail results in very-high-frequency analog signals. The older original analog TV was limited to frequencies of approximately 4.2 MHz. Modern HDTV uses much higher-frequency responses up to about 10 MHz. To see that picture detail, you must transmit the analog signal over a channel that has sufficient bandwidth. Most radio channels and cable systems have bandwidth limitations, and essentially act as a low-pass filter that will remove some of the higher frequencies. While you will still see a picture, it will lack some of the fine detail that your eye may or may not notice.

Resolution as it relates to DTV is a combination of how many scan lines plus how many pixels per line are used. Obviously, the greater the number of scan lines and the greater the number of pixels, the more detail you are going to be able to transmit and ultimately see.

A higher-resolution format to produce what we call high-definition (HD) TV uses 720 scan lines with 1280 pixels per line. The ultimate high-definition format uses 1080 horizontal lines with 1920 pixels per line. Both of those high-definition formats can use either interlace or progressive scanning at rates of 30, 60, 120, and 240 frames per second. Just remember that the frame rate simply refers to the number of times per second that each frame is presented on the screen. The earlier slow frame rates of 30 and 60 frames per second often produces a kind of picture smearing when the scenes are changing at a high rate of speed. This is noticeable in action movies or in sports events. The newer 120- and 240-frames-per-second scan rates essentially eliminate this problem.

Color Video Principles

Thus far, the signals we have described are what we call monochrome or black-and-white video. In *monochrome video*, all we capture and transmit and reproduce is the brightness variations along a scan line that range from black to white and an infinite number of shades of gray in between. But, of course, today most video is color. Capturing, transmitting, processing, and displaying color is a far more complex process than monochrome.

One physics principle that makes color video possible is the concept that any color of light can be reproduced by simply mixing the right combination of red, green, and blue light. Take a look at Figure 11.6. Mixing red and green creates yellow. Mixing red and blue produces violet (magenta), while mixing green and blue produces the color cyan. In any case, as it turns out virtually any color can be created using just the right mix and intensities of red, green, and blue. Strangely enough, there is one unique combination of the three colors that creates white. Black is produced, of course, by just turning off all the light sources. The color TV problem is how do you capture the individual colors and then how do you reproduce them?

Most video cameras use a light-sensitive imaging chip called a charge-coupled device (CCD). An optical lens focuses the scene on the chip. The chip itself is made up of millions of tiny light-sensitive elements that are charged like a capacitor with a voltage depending on the brightness level reaching them. The analog video signal for a scan line is then created by sampling those light-sensitive elements one at a time horizontally. The result is an analog signal whose amplitude is proportional to the light level. The result is a black-and-white brightness or Y signal.

Figure 11.7 shows how the color signals are produced. The scene is actually passed through a lens and a beam splitter that divides the scene into three identical segments. Each is passed through individual red, green, and blue filters. Three light-sensitive imaging chips (CCDs) then produce three separate analog signals for the red, green, and blue elements in a scene. The red, green, and blue analog signals are then individually amplified and sampled by an analog-to-digital converter (ADC) to translate them into a binary sequence. The three binary streams are then transmitted serially as a sequence of red, green, and blue for each picture element on the imaging chip. Each of these RGB colors will then later form a pixel on the viewing screen.

Video Compression

Generating a color video signal produces a serial bitstream that varies at a rate of hundreds of millions of bits per second. Consider these calculations:

- For each pixel, there are three color signals of 8 bits each making a total of $8 \times 3 = 24$ bits per pixel.
- For a standard DTV screen, there are 480 lines of 640 pixels for a total of 307,200 pixels per frame or screen.
- For one full screen or frame, there are $307{,}200 \times 24 = 7{,}372{,}800$ bits.
- If we want to display 60 frames per second, then the transmission rate is $7{,}372{,}800 \times 60 = 442{,}368{,}000$ bits per second, or 442.368 Mbps. That is extremely high frequency.

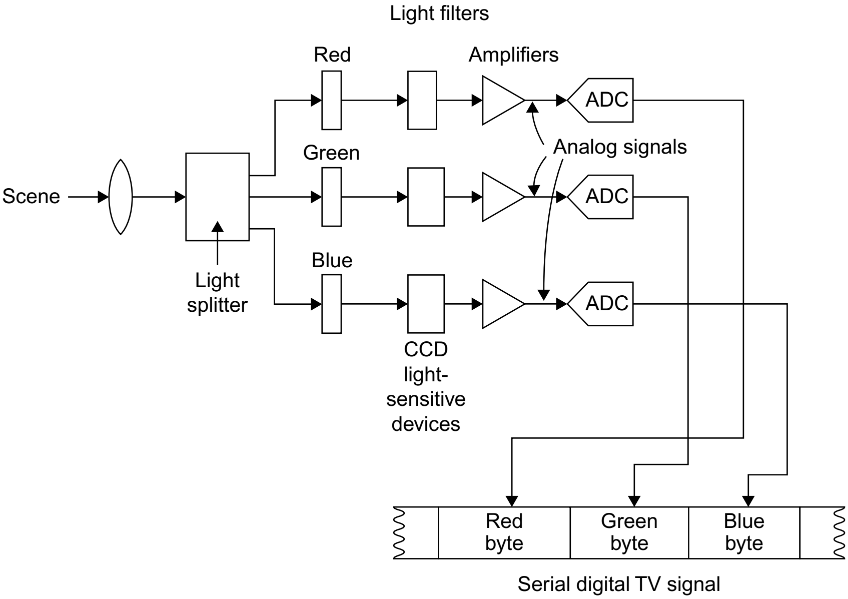

FIGURE 11.7 Red, green, and blue digital color signals are generated by filtering the scene into its red, green, and blue components, and then digitizing the resulting analog signals.

- To store one frame of video of this format, you would need a memory with 55,296,000 bytes or 55.296 MB. And that is just one frame.
- To store 1 minute of video you would need a memory of 3,317,760,000 bytes or just over 3.3 gigabytes (GB). And that is just 1 minute. Multiply by 60 to get the amount of memory for an hour.

Imagine the speeds and memory requirements for 1080p or a 120 frames-per-second format. And we have not even factored in the stereo audio digital signals that go along with this. Anyway, you are probably getting the picture here. First, data rates of 442.368 Mbps are not impossible, but they are impractical as they require too much bandwidth over the air and on a cable. And they are expensive. Furthermore, while memory devices like CDs and DVDs are available to store huge amounts of data, they are still not capable of those figures. Therefore, when it comes to transmitting and storing digital video information, some technique must be used to reduce the speed of that digital signal and the amount of data that it produces.

This problem is handled by a digital technique known as *compression*. Digital compression is essentially a mathematical algorithm that takes the individual color pixel binary numbers and processes them in such a way as to reduce the total number of bits representing the color information. The whole compression process is way beyond the scope of this book, but suffice it to say that it is a technique that works well and produces a bitstream at a much lower rate. And, the compressed video will take up less storage in a computer memory chip.

The digital compression technique used in digital TV is known as MPEG-2. MPEG refers to the Motion Picture Experts Group, an organization that develops video compression and other video standards.

What you have to think about when you consider the transmission of digital video from one place to another is that it is typically accompanied by audio. The audio is also in serial digital format. Those digital words will be transmitted along with the video digital words to create a complete TV signal.

TV Transmission

The compressed audio and video of a TV signal are assembled into packets or frames that look like that in Figure 11.8. The 4 bytes up front provide synchronizing bits for the receiver. The ID header tells the packet number, sequence, and video format used. The remaining bits are the serial compressed video and audio.

Figure 11.9 shows a simplified TV transmitter. The serial digital video is put through the MPEG-2 compression process. This is followed by additional

bit manipulation and coding for error correction and improved signal recovery by the receiver. This serial data is then multiplexed with the serial compressed audio data. Then the packets are formed. This is what will modulate the transmitter.

The modulation begins by translating the fast serial bitstream into an eight-level signal with a DAC. Each 3-bit segment of the serial data is assigned a specific voltage level as shown in Figure 11.10. Since each level represents 3 bits, you can transmit more bits per second in the same time period. It is this eight-level signal that modulates the transmitter carrier. The modulation is AM, where all of the upper sidebands are transmitted but only part of the lower sidebands. This saves spectrum. The modulation is referred to as 8VSB for *vestigial sideband*, where vestigial refers to part of the lower sideband. The signal is then up-converted to the final frequency by a mixer. A high-power amplifier in the transmitter sends the signal via coax cable to the antenna. Typical TV station range is about 70 miles maximum, and that is determined by tower height and terrain.

In the United States, each TV channel is 6 MHz wide. There are 50 channels starting at channel 2 from 54 to 60 MHz. Channels 3 through 6 range from 60 to 88 MHz. Channels 7 through 13 run from 174 to 216 MHz. Channels 14 through 51 run from 470 MHz and ending with channel 51 from 692 to 698 MHz.

FIGURE 11.10 U.S. ATSC system translates the digital bitstream into an eight-level signal to transmit multiple bits per level, making higher data rates in a given bandwidth possible.

TV Receiver

Figure 11.11 shows a general block diagram of a modern digital TV receiver. The signal from the antenna or cable TV box is sent to the tuner where the signal is amplified and sent to a mixer along with a local oscillator signal to down-convert the signal to a lower frequency called the *intermediate frequency*. This is commonly 44 MHz. The local oscillator is a frequency synthesizer that selects the desired channel, usually with a remote control. The IF signal is filtered to select only the desired 6-MHz channel.

The IF is then sent to an ADC for digitizing. The 8VSB signal is then recovered in the demodulator. It is then translated into the original bitstream, and any coding or error correction is removed. The signal is then demultiplexed into the video and audio streams. The video goes to an MPEG-2 decompression circuit for recovery of the original video. The individual RGB components are sent to DACs to recover the picture detail. The RGB signals are then amplified and sent to the screen for display. The audio is also decompressed and sent to the DACs and amplifiers and speakers.

The whole TV set looks something like Figure 11.12. Note all the possible inputs. The set gets its RF inputs from the antenna or cable box. The cable box may also have a digital signal output, meaning the cable box does all the decoding, demultiplexing, and decompression. The output comprises a serial data stream of the video and audio. A special high-speed digital interface called the *high-definition media interface* (HDMI) is used. It uses a special cable no more than 15 feet long and with a special 19-pin connector. The HDMI carries video and audio from the TV to cable box or DVD player or vice versa.

Most TV sets also accept analog video inputs from other sources like VCRs, video cameras, and digital cameras. A special fiber optic cable input called TOSLINK serves as the interface for TV sets, cable boxes, and DVD players.

Finally, some TV sets include standard computer interfaces like USB ports or the IEEE 1394 interface, a fast digital serial interface for video and audio developed by Apple.

TV set outputs, of course, are sent to the screen and the speakers. A remote control sends signals to an embedded controller that tells the set what to do.

TV Screen Technology

As indicated earlier, there are several ways that the video signal is translated back into a viewable picture. The cathode ray tube is still present in older sets, but LCD screens are by far the most popular and most widely used today. Plasma screens are still available but slowly fading away, and DLP projection screens are popular because of their low cost. There are other emerging technologies that we may see in the future. In any case, what we need is a light source to reproduce the varying intensities of red, green, and blue light.

Color video screens are made up of a very large number of tiny red, green, and blue light sources. These are used to make up the pixels or dots of light

that re-create the picture. These pixels are very small, so that your eye cannot actually see them even when you are relatively close to the screen.

Figure 11.13 shows some of the screen pixel formats in use today. Cathode ray tubes were made up of a group of three color phosphor as shown in Figure 11.13A. These color triads were grouped tightly together to form the complete screen. When an electron beam strikes each of the red (R), blue (B), and green (G) pixels, they cause the phosphor dots to glow. The eye automatically mixes the individual red, blue, and green colors to reproduce the desired color.

LCD and plasma screens use a pixel format somewhat like that shown in Figure 11.13B. These are usually rectangular red, green, and blue areas that are backlighted with the appropriate degree of intensity.

One pixel is not necessarily equal to the three color group shown in Figure 11.13A. Instead, 1 pixel as displayed on the screen might actually be made up of a collection of these individual groups. The actual pixel size may be something like Figure 11.13B, made up of multiple groupings of red, blue, and green elements as shown.

The actual format displayed on the screen is determined by the TV display standards. As indicated earlier, a standard DTV screen uses 480 horizontal lines with 640 pixels per line. That creates a screen with a total of 307,200 pixels. The 720 × 1280 screen puts 1280 pixels on 720 lines for a total of

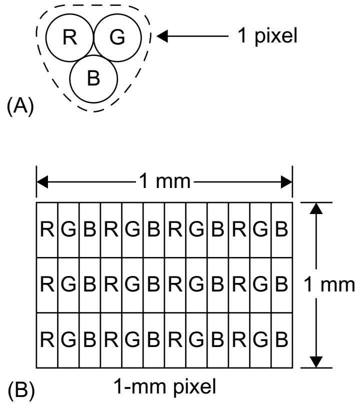

FIGURE 11.13 How color pixels are formed on a TV screen. (**A**) Pixel format for most CRTs. (**B**) Pixel format typical of LCD, plasma, or LED screens.

921,600 pixels. The big daddy of all screens uses 1080 lines with 1920 pixels per line for a total of 2,073,600 pixels. Just remember that the pixels are turned on one at a time from left to right and top to bottom on the screen at a very high rate of speed.

Summary of Screen Technologies

The actual technical details of each of the different types of screens are way beyond the scope of this book, but a summary might be useful. A quickie review of each of these screen types follows.

CRT—A cathode ray tube contains three electron-beam guns, each one driven by the analog color signals from the DACs. The intensity of the electron beam depends on the intensity of the light and color signal being fed to it. These electron beams are aligned so that they strike the red, green, and blue phosphor dots covering the screen. Each dot emits light with an intensity proportional to the strength of the electron beam striking it. The electron beams are scanned simultaneously across the screen at very high speed, stimulating the pixels in the right proportion to reproduce the desired color.

LCD—Liquid crystals are, as their name implies, a liquid made up of molecules whose physical orientation can be changed by the application of an electric signal. Different voltages change the polarization of the light through the liquid. By applying one level of voltage to the liquid crystal, it can be made almost totally transparent where maximum light passes through it. Another level of voltage will twist the molecules and practically block all light from being passed. In this way, the liquid crystal acts almost like a camera shutter but in this case with varying degrees of transparency being possible. The liquid crystal material is contained within glass plates. A bright light source such as a fluorescent lamp or high-brightness LEDs are placed behind the liquid crystal.

In front of the liquid crystal is another transparent sheet containing the red, blue, and green pixels described earlier. The whole thing is sandwiched together in a very thin screen. The electrical signals applied to a matrix of wires cause the liquid crystals to be properly oriented for each pixel and to allow the correct proportion of light through to each of the red, blue, and green light filters.

Plasma—A plasma screen is also made up of many tiny light sources. Each light source or subpixel is actually a small chamber containing xenon and neon gases. When a voltage is applied to each of these chambers, the gases ionize and emit ultraviolet light. The ultraviolet light then actually strikes a phosphor coated inside the chamber. The chamber then emits red, green, or blue light. The degree of ionization determines the brightness of each subpixel. In any case, electrical signals are then applied in sequence to the subpixels to turn them on with the correct degree of brightness to produce the desired color.

DLP—Digital light processing is a technique invented by Texas Instruments. The heart of it is an integrated circuit chip made up of hundreds of thousands or millions of tiny mirrors. The mirrors can be moved to one of two positions. This is an example of a *microelectromechanical system* (MEMS). MEMS is a technique for making mechanical moving objects using semiconductor manufacturing techniques.

Each of the tiny mirrors can be moved so that in one position it will reflect maximum light (representing white) and the other position where no light is reflected (representing black). You can then produce any shade of gray simply by switching the individual mirrors off and on at a high rate of speed. The light source is shined on the mirror and the resulting monochrome scene produced on the DLP chip is then focused on a screen from the rear by a lens system.

To produce color, the light source is passed through a rotating disc with alternating red, green, and blue segments. The speed of rotation and the frequency of each color on the disc allow each mirror to then reflect a specific color of light. In the newer DLP screens, high-intensity red, green, and blue LEDs are used to send light to the mirrors, which are then mixed and projected onto the screen.

LED—The newest TV screens are made of tiny red, green, and blue light emitting diodes arranged in a pixel matrix as described earlier. The LED screens are the brightest available and respond fast to action scenes. However, they are the most expensive screens.

3D TV

Yes, you actually can buy a 3D TV set that gives you that same 3D “coming-at-you” feeling of theater 3D. As this is written, these sets are very expensive and there is very little 3D material to see. Right now it is only available on DVD. Eventually it may be available by cable or satellite or over the Internet. And, yes, you still have to wear the special glasses. These glasses are not the red and green lens type but a special electronic version. The lenses use electrical polarization like a shutter that turns the left and right lenses off and on

Which Screen Type Is Best?

It is very difficult to find a new TV set with a CRT. You can still buy them, but they are typically only available in the smaller screen sizes such as 9, 13, and 19 inches.

LCD screens are available in a wide range of sizes, but the minimum today for a TV set is about 19 inches. Remember that these dimensions are the diagonal dimension from an upper corner of the screen to the lower diagonal corner. The most popular LCD screen size is 32 inches, but they are available in a wide range of sizes from about 42 to 65 inches. Even bigger ones are available. Plasma screens come in sizes from about 42 inches to about 70 inches. A DLP screen can be had in sizes from 50 to 100 inches.

As for prices, LCD and plasma screens are approximately comparable. DLP projection screens are significantly less expensive for the same size.

There are a couple of other factors to consider in evaluating screen types. As far as brightness goes, they are all very good, with the DLP probably slightly less bright than the other two types. Contrast, meaning the ratio of the brightest white to the darkest black, is also excellent on all types of screens, a little bit less so on the LCD.

Viewing angle means whether you can see the picture from any angle. Most screens are viewed directly straight on, but many viewers are off to the side or at an angle. DLP screens generally have poor viewing angles: when you get too far off to the side, you will not be able to see the picture or it will fade away. LCDs have this problem but to a lesser extent. Plasma screens have the widest viewing angles.

Finally, the ability of a screen to produce high-speed motion is generally excellent on plasma and DLP screens. LCDs did produce some smearing, but recently the higher scan rates of 120 and 240 frames per second have essentially eliminated this problem.

LCD screens dominate TV today and are gradually replacing all other types as their price continues to drop with better manufacturing methods. Plasmas and DLP are still available but are gradually fading. LED screens are growing in popularity and will become more widely used as prices come down in the future.

in synchronization with the two alternating sets of frames on the screen. A wireless signal (IR or radio) signals the glasses when to switch. The switching occurs at very high speed so the effect is to see the 3D scene. Only time will tell if this is just a gimmick or niche TV product.

CABLE TELEVISION

It is estimated that about 15% of all U.S. citizens get their TV over the air with an antenna. But over 70% get TV via cable. The remaining 15% get satellite TV. Why? Mainly because cable offers not only better, more reliable signals than by antenna, but also offers hundreds of channels of programming. But that's not all. Most of those who have cable also use the cable connection for

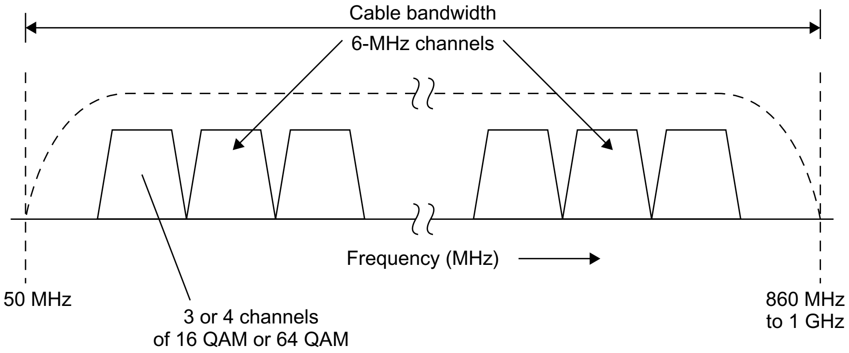

FIGURE 11.14 Coax cable bandwidth up to 1 GHz can contain about 130 6-MHz channels.

high-speed Internet access service. Of course, you pay for all that, and it has become like a monthly utility bill. With the cable industry being so big, it pays to know a little more about it.

It all starts with a facility called the *cable head end*. Another name you might hear is cable modem termination system (CMTS), which specifically is the equipment at the head end. This is a place where the company collects video and programming from many different sources. It snatches signals off the air, it receives premium programming like HBO, ESPN, Showtime, and Fox via satellites, stores movies on its large computers called video servers, and may even do some of its own local programming. The result is a hundred channels or more.

Now each of those TV signals—video plus audio—is modulated onto carriers that are spaced 6 MHz apart just like the regular over-the-air TV channels. Then all of those modulated carriers are added together to form a very complex signal. That signal is then amplified and put on the outgoing cable. Figure 11.14 shows what the spectrum looks like. Most cables have a bandwidth from about 50 MHz up to about 860 MHz to 1 GHz, which will accommodate up to about 130 6-MHz channels. We call this process frequency-division multiplexing, where a single cable can carry many separate channels of data, each on a different frequency and bandwidth. And since the cable is shielded, it does not radiate, so it, in effect, duplicates the free-space electromagnetic spectrum.

Since most TV today is digital, digital modulation methods are used to put multiple TV signals within each 6-MHz channel. Using 16-QAM or 64-QAM, a cable company can squeeze several channels of video/audio into each 6-MHz chunk of spectrum, providing hundreds of additional slots for programming. That is why cable companies can advertise up to 500 channels of entertainment, news, and so on.

All of the digital video/audio signals are then remodulated onto different channel assignments. All of these 6-MHz channels are added together or linearly mixed in a multiplexer (MUX) to create a massively complex composite signal. This is what goes out on the cable (see Figure 11.15).

FIGURE 11.15 General block diagram of modern cable TV system.

The signal distribution network is called a *hybrid fiber cable* (HFC) system. This multiplexed signal is applied to a fiber optic cable, called a *trunk cable*. It is routed around the city and it terminates at selected points where the signal is divided into multiple paths of coax cable. These so-called *feeder cables* are connected to amplifiers along the way to overcome the large attenuation of the cables. At some point, the feeder cables come into your neighborhood and are further amplified and split into multiple signals. These signals are then sent to your house by a coax drop cable. The most common type is 75-ohm RG-6/U coax with F-connectors. The cable comes into your home and is usually split two or more times and sent to wall connectors in the various rooms. These connectors connect the signal to a cable box and/or a cable modem for the PC.

The cable box is like a tuner in that its main job is to select one of the many channels and send it to your TV set. Figure 11.16 shows a simplified block diagram of a typical cable box, usually called a set-top box (STB). The input is a TV tuner with channel selection via a frequency-synthesizer local oscillator by way of your remote control. The selected signal is then demodulated and decompressed by a digital media processor chip, and then sent to the TV set via one of the many possible interfaces, usually the HDMI or *high-definition multimedia interface*. This is a very fast digital interface with special cable and connector. Most TV sets have this as the most common input. Other video format interfaces such as RGB, PrPbPy, or S-video, are usually provided to accommodate older analog TV sets. An additional feature of many of the newer STBs is a built-in digital video recorder (DVR). This is essentially a computer hard disc drive that records the program you want to save for viewing later.

Other Wired TV Distribution Systems

There are a couple of other ways that digital video is distributed to homes. One is a fully fiber optic system. The fiber cables go all the way from the head end to the homes. This was once too expensive, but today, thanks to improved fiber and other technologies, it is cost effective. Such systems are generally referred to as *passive optical networks* (PONs). "Passive" simply means that the signals are strong enough and the cable runs short enough so that no amplification is needed along the way. The digital video and audio are modulated onto infrared (IR) light beams and sent down the cable. Because fiber has such wide bandwidth, data rates are extremely high, over 1 GB/second in the newer systems. This allows not only digital video to be transmitted but also very-high-speed Internet service. Such systems use standards like Ethernet PON or GPON for gigabit PON. A typical U.S. system is Verizon's FiOS.

Another new system is called IPTV for *Internet protocol TV*. This is video distribution via putting the compressed video on a fiber optic cable using the familiar TCP/IP protocols. The signals travel via fiber to the neighborhoods. From there they are split off and the signals travel via in-place twisted-pair telephone lines.

(*Continued*)

Other Wired TV Distribution Systems (Continued)

New forms of modems using a form of OFDM called *discrete multitone* (DMT) transmit the signal over the twisted pair at high speeds. These lines are now used just for high-speed Internet service and are referred to as *asynchronous digital subscriber lines* (ADSL or just DSL). Newer versions called ADSL2 and ADSL2+ or VDSL for video DSL provide data rates from 26 to 52 Mbps on standard phone lines. An example of a system in the United States is AT&T's U-verse system.

For Internet access, you connect a cable modem to the coax cable and it automatically selects the channel where the data services are assigned. The modem goes to your computer via an Ethernet cable. Access to the Internet is by way of your computer's browser.

SATELLITE TV

Satellite TV technically is also over-the-air TV or radio, but instead of the signals coming from one or more local TV stations, broadcast towers, the signals emanate from a geosynchronous satellite 22,300 miles away orbiting around the Equator (see Figure 11.17). The satellite transponders operate in the Ku band with frequencies of 10.95 to 14.5 GHz. This system is referred to as *direct broadcast satellite* (DBS).

The satellite TV company gets its TV like the cable companies, and brings it all together at a single Earth station head end where it is all collected and transmitted on an up-link to the satellite in the 14- to 14.5-GHz range (see Figure 11.18). The signals are then amplified in the satellite and rebroadcast on the down-link frequencies at 10.95 to 12.75 GHz. A high-gain antenna focuses the signals on the United States or other country of interest.

Down on Earth, satellite TV subscribers have a special receiver and antenna. These are illustrated in Figure 11.19. The antenna is usually a small dish or parabolic reflector antenna about 18 inches in diameter. The antenna is usually a small horn. Also inside the antenna assembly is a low-noise amplifier (LNA) to boost the small signal from the satellite. This is then sent to a mixer along with a local oscillator signal to down-convert the signals into the 950- to 2100-MHz range. This signal is then routed by coax to the satellite receiver. The LNA/mixer assembly at the antenna is called a low-noise block (LNB) converter. This receiver signal processing at the antenna is necessary because the Ku band frequencies of 10.95 to 12.75 GHz are so high they would be far too greatly attenuated by the antenna coax cable to the receiver. So down-converting to the lower frequency allows coax to be used to the receiver.

The satellite receiver is like the cable box in that it is used to select the desired channel and demodulate it for the TV set. The satellite signals are all digital and transmitted in packets 147 bytes long. A satellite receiver is shown in Figure 11.20. MPEG-2 video decompression is used. The recovered signals

are then sent to a digital TV receiver, typically via an HDMI port. Or in older systems, the video and audio are remodulated on a channel 3 or 4 TV carrier and sent to an analog TV set.

CELL PHONE TV

You knew it would come. Actual TV on your cell phone. You can easily get video via the Internet connection on a 3G phone over the network or via a Wi-Fi hot spot. Typical video is like that from YouTube or just video clips that users attach.

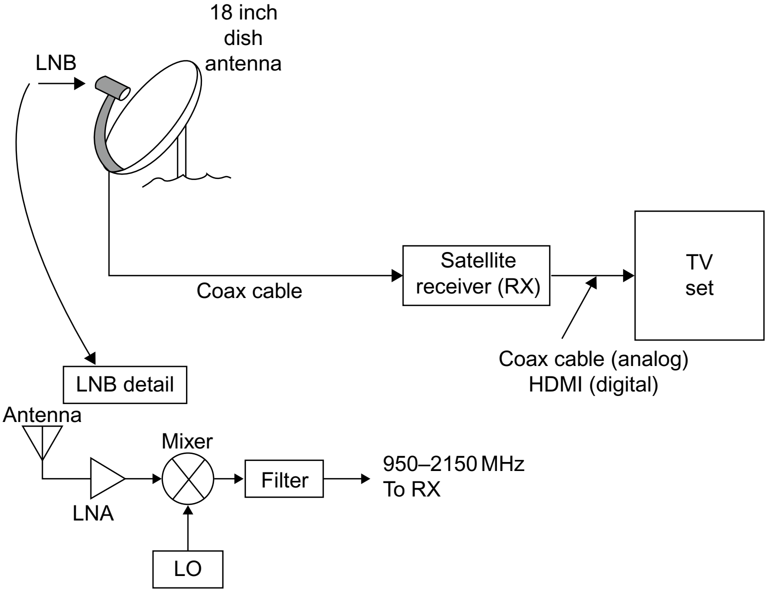

FIGURE 11.19 Satellite TV home system consists of antenna with low-noise block converter, receiver, and TV set.

Some cellular carriers also offer several video channels over the network for an extra fee each month. Such video is available from AT&T and Verizon, and consists mainly of news, weather, sports, and a few comedy channels.

Since video is so data intensive and requires lots of extra bandwidth and high speeds, too much video service can overload most cellular networks. It has been decided that the best way to deliver TV service to a cell phone is to broadcast it. Several methods are being implemented. For example, in Europe the DVB-H system is being used to broadcast programming to handsets. Similar systems in Japan and Korea are also used. Both are digital. In the United States, MediaFLO broadcasts video to handsets on the old TV channel 55 (716 to 722 MHz). It uses OFDM and about 15 to 20 channels are available. The service is provided for a monthly fee.

In the near future, standard ASTC digital TV will be available in the United States. A special version for mobile handsets has been developed and will likely be adopted by existing TV stations for broadcast to cell phones. This is expected to be free TV, but no doubt ads will be used to pay the bills. If making a phone call or texting by cell phone is distracting to drivers now, wait until TV is available. (Now that is something to look forward to.)

and today on the streets. The video signals are routed to a central point where multiple TV sets or monitors are set up for observation.

In many installations, the video is transmitted directly over coax cable to the monitors. There is no modulation involved. However, in some cases, when remote cameras are used, a wireless link via 2.4 GHz is typical. Of course, modulation is then used in the transmission so that a receiver is needed at the viewing end to recover the video.

Many installations also have video recorders (VHS tape or DVD) to capture several minutes or hours of video. In the past, most cameras were black and white, but today more and more use color.

DIGITAL VIDEO DISCS

The formal meaning of DVD is *digital versatile disc*. Its main use is video but it can also store computer data or audio. It is the storage medium of choice for movies, music videos, and other video programming. It has virtually replaced the VCR.

The basic DVD storage medium is a disc that is almost identical to the CD discussed in Chapter 10. The disc is the same size (120-mm diameter), but it is formatted differently to store many more bits and bytes of data. While the CD can store up to about 700 MB, the DVD can store about 4.7 GB, that is, gigabytes or billions of bytes. And that is just the basic one-sided disc. There are also single-side/double-layer discs, double-sided/single-layer, and double-sided/double-layer versions that can store even more, up to 15.9 GB.

The storage method is the same. A laser beam burns pits into a spiral track. The data is represented as pits and lands as described earlier in the CD discussion (see Figure 10.6). The big difference is that the size of the pits is significantly smaller and the track spacing is less than half the CD spacing, that is, 1.6 microns (1600 nanometers) versus 740 nanometers (nm). A nanometer is 1-billionth of a meter. With smaller pits and tighter spacing, the disc can hold significantly more data.

But that is not the whole story. The video is also compressed. Unlike the audio on a CD, which is not compressed, digital video is compressed with the MPEG-2 standard described earlier. This gives roughly a 40-to-1 compression. In that way, a full 2 hours of video can be stored.

As for audio, the format is as described in Chapter 10 for CDs, but DVD audio is Digital Dolby Surround Sound 5.1 using six channels of 16-bit, 44.1-kHz digital sound. Audio DVDs are also available with 192-kHz sampling of the audio with 24-bit ADCs, giving even greater fidelity and low-noise performance.

How a DVD Player Works

Figure 11.21 depicts the block diagram of a typical DVD player. First, note the motor that drives the disc. It is a variable-speed device that changes speeds as the pickup mechanism moves from inside to outside as it reads the spiral track.

The pickup head uses a laser that shines on the disc to read the pits and lands. Because of the closer spacing, a higher-frequency (shorter wavelength) laser is used. CD players use a 780-nm laser, while DVD players use a 640-nm laser that has a smaller focused beam.

The photodetector in the head picks up the laser reflections and sends the 10 Mb/second data stream to the processing chips. In some players, a single-chip application-specific device handles all of the digital processing from demultiplexing, to error detection and correction, decoding, and MPEG-2 decompression. All this may be in separate chips in some players.

In any case, the MPEG-2 data goes to a video decoder and to multiple DACs that re-create the original analog RGB signals. Various video formats are used, such as RGB, YCrCb, and YPrPb, each of which needs three DACs each. Most DVD players also decode regular composite video and S-video.

The separated audio signals go to an audio codec that contains the DACs which recover the audio content either in basic stereo or 5.1 surround sound. As for interfaces, an HDMI output is provided. Most players also have an Ethernet port, IEEE 1394, and USB connections.

Don't forget that some of the later models are also DVD recorders. They play DVDs but also burn new ones with video from the TV set, cable box, satellite box, or a built-in tuner.

A Word about Blu-ray

Blu-ray is the next generation of DVD medium and players. The discs are the same size but thanks to even smaller pits, lands, and track spacing, even greater storage capacity is available. With 320-nm track spacing and a 405-nm (blue light wavelength) laser, the single-sided disc can hold up to 25 GB of data. That is enough to store two full-length high-definition movies or 13 hours of standard-definition video. A double-layer version is also available that doubles those storage figures. Blu-ray uses MPEG-2 compression, but also supports other video compression standards such as MPEG-4/H.264 and VC-1.

For a while, there were several other video disc standards competing for dominance. The most notable was HD-DVD, which did bring players to market. Most movie companies and other media sources selected Blu-ray as the distribution medium, making Blu-ray players the de facto standard and eliminating HD-DVD.

Industrial Control

How to Automate: Monitor, Process, and Control

In this Chapter:

INTRODUCTION

Industrial control is one of the four major applications of electronics. In industrial control, electronic components, circuits, and equipment are used to operate various types of machines in manufacturing plants. Most industrial machines like robots are mechanical in nature but electrically operated. Most are powered by electric motors or other actuators. To operate the machine, electrical power must be properly controlled. Industrial control electronics is used to turn machines off and on at the appropriate time, control their speed of operation, and otherwise produce the desired manipulations.

Electronic control is not confined to industry. There is lots going on in the home and car as well. The principles given here apply to those applications as well.

OPEN- AND CLOSED-LOOP CONTROL

The basic industrial control process is illustrated in Figure 12.1. Electrical inputs, such as switches, sensors, or other devices, are used to initiate an electronic control process. The signal-processing circuits generate control output signals that are used to operate the industrial machines. This basic process is known as open-loop control. The typical device being controlled by the output signals is an electric motor that operates a machine. Other outputs could operate lights, relays, solenoids, or a variety of other devices.

Open-Loop Control

A simple example of an open-loop control system is shown in Figure 12.2. The input is a switch that applies electrical power to a motor. The motor, in turn, operates a pump that causes liquid to be put into a vat or tank. As soon as the vat is full, the operator turns the switch off. The basic control process in this system is simply turning power off and on to control the pump. The operator visually monitors the level in the vat until the correct level is reached.

Closed-Loop Control

An improved form of industrial control system is illustrated in Figure 12.3. It is known as a closed-loop control system. The system is given an initial input

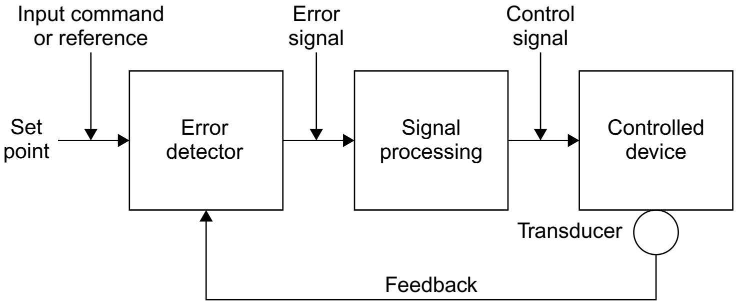

FIGURE 12.3 Generic diagram of any closed-loop control system with feedback.

reference called the set point. The set point is usually a voltage that represents some physical value that is to be achieved. It is applied to an error detector that compares this input to a signal from the controlled devices. If the two signals are different, an error output is produced. This error signal is processed (usually amplified), and an output control signal is derived from it. It is this output signal that operates the controlled device. A transducer monitors the controlled device to see that the desired outcome is obtained. The signal from this transducer is called *feedback*. The feedback signal is compared to the input to produce the error signal. The control signal operates the controlled device until the error is reduced to zero. At that time, the desired output condition, where the feedback equals the set point, is obtained.

The key to closed-loop control is the feedback. Feedback signals tell the system whether the machine is performing correctly. The feedback signal allows the system to adjust itself in such a way that the desired output is continuously accomplished. Control is automatic.

A closed-loop version of our system to fill a vat with liquid is shown in Figure 12.4. An initial input signal is applied to start the process. If the vat is not full, the transducer will sense it and send a signal to the error detector that says the liquid level is low. The error detector generates an output signal that is processed and used to start the pump motor. The motor rotates the pump, which puts liquid in the tank. When the vat is full, the sensor will generate a signal that is sent to the error detector. The error is now zero, so the pump motor is turned off.

The primary benefit of a closed-loop control system is that its operation is automatic. In the open-loop system, an operator has to turn the system off and on manually to fill the tank. In the closed-loop control system, the operator gives an initial input, called the set point, to which the error detector will compare the feedback signal from the sensor. He or she turns the system on. From that point on, operation is automatic. The pump turns itself off when the vat is full. If the liquid level drops below the desired level due to usage, the sensor indicates a low level and automatically turns on the motor so that the pump will again fill the tank. When the tank is full, the unit shuts off by itself.

FIGURE 12.4 Filling vat with liquid automatically with closed-loop control system.

Most industrial control systems are closed loop to make them automatic. And your home has some as well. Your toilet flusher is a closed loop as is your heating and air conditioning (HVAC) thermostat. Appliances like your washer, dryer, and dishwasher are other examples of closed-loop control. All of them contain a microcontroller with sensors, timers, and feedback to make them totally automatic.

Controllers

While many industrial control applications are implemented with simple control circuits, most industrial control is carried out by specialized instruments called controllers. These units accept inputs from sensors, condition them, process them, and then generate output control signals.

A good example of an analog controller is one used to control the temperature in a system. A resistive temperature sensor is used to monitor the temperature of the liquid in a pipe. If the temperature goes up, the sensor output goes up. This is sensed by the controller circuitry. Inside the controller, a comparator is set to a desired temperature threshold. Should the temperature exceed a specified set point, the controller will turn off the device heating the

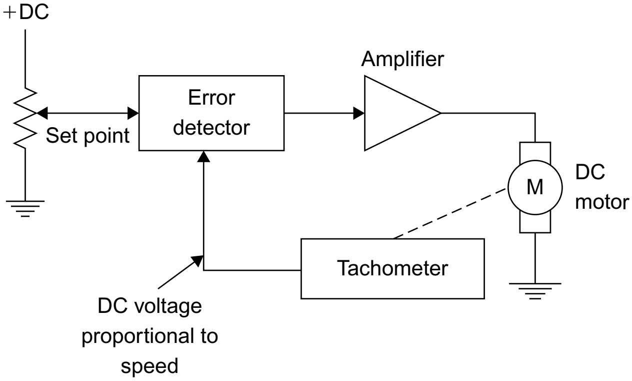

FIGURE 12.5 Closed-loop control system for motor speed control and regulation.

pipe and liquid. Should the temperature drop below another set point temperature, the controller will turn on the heating device in an effort to maintain the set point temperature. While the heating element will be turning off and on, it will produce the desired average overall temperature.

A continuous analog controller will provide proportional control rather than an off/off response. For instance, suppose that you want to control the speed of a motor. The system depicted in Figure 12.5 does this. You want the motor to stay set to the speed you want, say 1200 rpm. A pot connected to a voltage represents that speed value. The voltage is applied to an error detector along with the feedback input from a tachometer. A tachometer is a device that senses rotational speed and develops a proportional DC voltage. That voltage is sent to the error detector and compared to the set point. If they are different, an error voltage is developed. This voltage is then amplified and applied to the motor. The speed of a DC motor is proportional to the voltage applied to it. So if the motor slows down, the error voltage is increased and that is amplified and applied to the motor speeding it up to compensate for the speed drop. A speed up in the motor produces an increased tachometer output. The resulting error signal causes the motor speed to drop until the error is zero. With such a circuit, the motor speed remains constant.

An analog controller is a product made up of the set point pot, error detector, and a selection of amplifiers whose gain can be varied and an output amplifier that can drive the motor or other device. Many different types of commercial electronic controllers have been developed to monitor and control physical characteristics such as pressure, physical strain, weight, liquid flow rate, physical position, or liquid level in a tank. Digital controllers that contain a microcomputer are also available.

SENSORS

An essential element of most control systems is the inputs from sensors. Sensors are the components that detect physical changes or events and convert them into

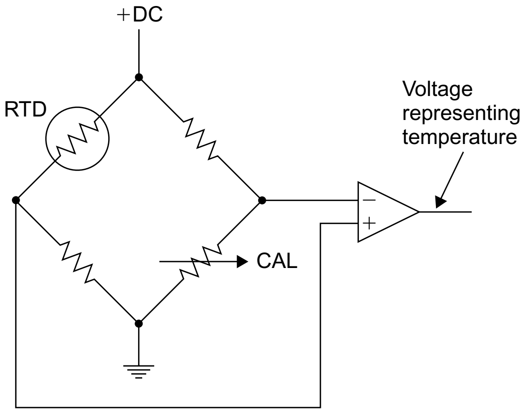

FIGURE 12.6 Most resistive sensors like an RTD or thermistor are placed in a bridge circuit to condition them to provide amplified output voltage.

electrical signals to be processed. Sometimes the term transducer is used to refer to the sensor. A transducer is a device that converts one type of energy into another such as mechanical energy to electrical. There are literally hundreds of different types of sensors. A few examples of the most common types follow.

Temperature Sensors

Temperature is probably the most often sensed physical characteristic. Temperature sensors convert temperature to a resistance change or voltage change. The most commonly used temperature sensors are RTDs, thermistors, and thermocouples.

RTD—An RTD is a resistive temperature device. It is essentially just a platinum wire whose resistance varies with temperature. Most of them have a resistance of 100 ohms at zero degrees Celsius (0°C). As the temperature changes, the resistance changes to reflect the change. RTDs have what we call a linear positive temperature coefficient. That is, as the temperature goes up the resistance goes up and vice versa.

To convert the resistance variation into a voltage, the RTD is usually put into a bridge circuit as shown in Figure 12.6. The bridge is initially balanced with the variable calibrate control (CAL) to produce zero output at a given temperature. Then if the temperature varies, the bridge becomes unbalanced and a voltage is produced. This is then amplified into a larger voltage that is a measure of the temperature. The output can be measured with a meter or it can be digitized for use as in input to a digital system for display or control.

Thermistor—A thermistor is a resistor whose resistance has a negative temperature coefficient. As temperature goes up the resistance goes down and vice versa (see Figure 12.7A). The resistance change is much greater than that

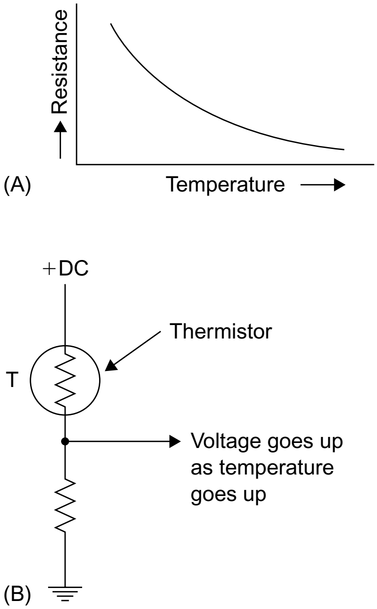

FIGURE 12.7 Characteristic curve of thermistor and simple voltage divider circuit producing output voltage.

of an RTD. The thermistor can be used in a simple voltage divider to develop an output voltage or in a bridge circuit like the RTD (see Figure 12.7B).

Thermocouple—A thermocouple is a unique type of temperature sensor, as it develops a voltage rather than a resistance change. It is formed with two dissimilar metals. If the junction of the metals is heated, a voltage is developed. The voltage is usually in the millivolt range so that it usually has to be amplified before it becomes useful. The thermocouple's main advantage is its accuracy at very high temperatures.

Solid State—Diodes and transistors make good temperature sensors. A silicon diode has a very linear voltage drop variation that decreases with an increase in temperature. This is true of the emitter-base junction of a bipolar transistor as well. Zener regulator diodes exhibit a similar response. The sensor is usually packaged into a complete integrated circuit with an amplifier that produces a voltage output proportional to the temperature variation.

Pressure Sensors

A pressure sensor responds to force or pressure. There are many different types. A widely used kind is called a *strain gauge*. A strain gauge is essentially a thin pattern of metal deposited on a plastic base like that shown in Figure 12.8. It has a specific value of resistance. A value of 120 ohms is common. The strain

FIGURE 12.8 Strain gauge is a resistive element whose value changes with stress or pressure.

gauge is then glued or cemented with an adhesive to the object to which the pressure is to be applied. An example is a steel beam. When pressure is applied to the beam, it will bend. As it bends, it stretches or compresses the strain gauge resistance element. If the resistive element is stretched, its resistance increases. If it is compressed the resistance decreases. Knowing the specific characteristics of the resistance change per pound of pressure, an exact measure of the pressure can be determined. Mostly strain gauges are used in a bridge circuit like that shown in Figure 12.6. Since the resistance variation is small and the resulting bridge circuit output is small, a special amplifier called an *instrumentation amplifier* is used. It has differential inputs and very high gain.

A special pressure sensor called a *load cell* is typically made up of strain gauges. It is fully calibrated to provide a specific voltage output with a specific pressure. Load cells are widely used for weight measurement. An example application is the use of load cells in truck weighing scales.

There are other forms of pressure transducers. Many are solid-state devices with an output voltage proportional to pressure. *Piezoelectric pressure transducers* use the voltage produced by certain types of crystals or ceramics when pressure is applied to them.

Switches

Switches are widely used as sensors. Switches are mechanical devices with electrical contacts that open or close with a particular physical movement. Switches are used to detect mechanical movement and specifically to determine when the limit of some physical device has been reached. Called *limit switches*, these devices have various arms and mechanisms that permit ease of use in a variety of situations. Examples of such switches are those that can detect when a cabinet door is open or closed or a switch that senses when a mechanical device reaches a specific point where motion must be stopped. And

of course, a human-operated switch may be the most common. It is usually a button that is pushed to initiate or stop some action.

Potentiometers

A potentiometer is a variable resistor or variable voltage divider. While most electronic pots are rotary devices, they also come in a linear variety. The variable arm of the pot is controlled by some external mechanical device. Then by using the resistance value of the pot or the voltage it produces as a variable voltage divider, it can be used to sense mechanical position.

Photoelectric Sensors

One of the most widely used industrial transducers is a photoelectric sensor. A photoelectric sensor is a component that responds to light and produces an electrical signal that can initiate some operation.

There are three basic types of photoelectric sensors. These are the *photoresistive* or *photoconductive cell*, the *photovoltaic cell*, and the *phototransistor*. The photoconductive sensor is a light-sensitive resistor. Its schematic symbol is shown in Figure 12.9A. The resistance of the device varies with the amount of light falling on it. With no light falling on the sensor, its resistance will be very high, 100,000 ohms or more. When bright light shines on the sensor, however, its resistance will drop to a very low value, usually several hundred ohms or less. Of course, at a light level between bright and dark, the resistance of the device will be somewhere between 100 ohms and several hundred thousand ohms. The resistance is inversely proportional to the light level.

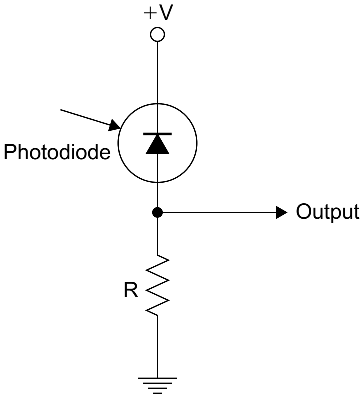

FIGURE 12.10 Photodiode and its simple output circuit.

Another type of photoelectric device is the photovoltaic cell, whose schematic symbol is illustrated in Figure 12.9B. This is the solar cell described in an earlier chapter. Whenever bright light falls on the cell, it will generate a small DC voltage. The maximum output of a typical photovoltaic cell is approximately 0.45 to 0.5 volt. At lower light levels, the output voltage will be less. Photovoltaic cells are used primarily in power generation systems for producing charging voltage for batteries in satellites and other remote systems. Multiple cells are connected in various series and parallel combinations to get the desired voltage level and current capacity. In some applications, the photovoltaic cell can be used for industrial control. These are also found in portable calculators. Two AA cells at 1.5 volts each produce 3 volts in series. To generate 3 volts with 0.5-volt solar cells, you would need to connect six in series ($6 \times 0.5 = 3$ volts).

A silicon diode can also be used as a light detector. Special diodes in clear housings are often used to detect light. These are called photodiodes. Photodiodes are operated in the reverse-biased direction, as shown in Figure 12.10. With no light falling on the diode, it is cut off, so there is no voltage across R_1. When light strikes the diode, its reverse leakage current increases dramatically, causing a voltage drop to occur across R_1.

A phototransistor is a light-sensitive transistor. Its symbol is given in Figure 12.9C. It only has two terminals, the emitter and the collector. The device has a base, but typically it has no lead. Instead, the device is built so that when the base is exposed to light, it will cause the emitter-base junction to conduct. When light strikes the base, it causes ionization, which simulates base-current flow. Therefore, the transistor conducts between emitter and collector. The primary advantage of a phototransistor is its very high sensitivity over a photodiode. It will conduct even with a small amount of light applied to the base. The transistor essentially provides amplification so that small light levels can control a large current.

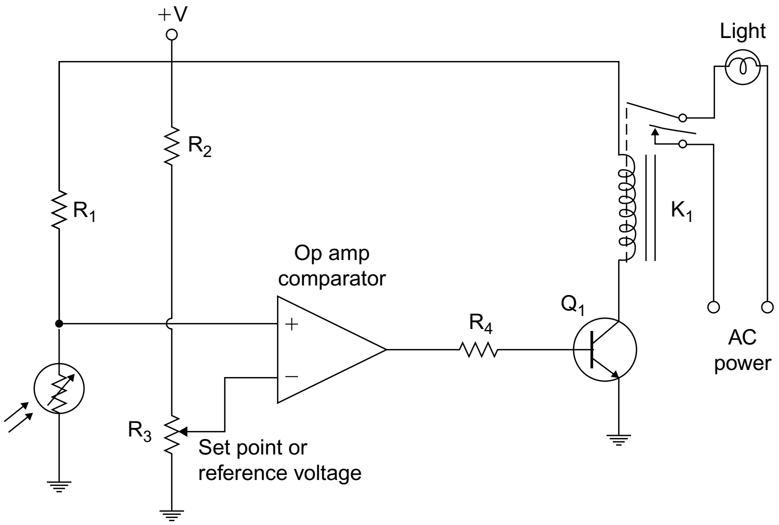

FIGURE 12.11 Simple off/on photo control circuit. Light turns on automatically at dark and off when light is present.

A typical closed-loop control circuit using a photoelectric cell is illustrated in Figure 12.11. This circuit will automatically turn a light on when it gets dark and turn the light off when it is light again. Note that a photoresistive cell is connected as part of a voltage divider with resistor R_1. The DC voltage from this voltage divider is applied to one input of an op amp comparator. The DC reference input to the comparator comes from a voltage divider made up of R_2 and R_3. The potentiometer can be used to adjust the DC reference voltage or set point. The output of the comparator drives a switching transistor Q_1, which will turn the relay K_1 off or on. This, in turn, operates the light.

When the photoresistive cell is exposed to light, its resistance will be very low. Therefore, the voltage from the voltage divider will be low. It will be less than the DC set point voltage and the comparator will not be triggered. The output of the comparator will be a negative voltage, which will reverse bias the emitter-base junction of the transistor and keep it turned off. As soon as it gets dark outside, the resistance of the photocell will increase. This will cause the voltage-divider output to increase. At some point, the voltage will be higher than the set point voltage, causing the comparator to switch. This applies a positive voltage to the transistor base, turning it on, and then turning on the relay and the light. The light will remain on as long as the photoconductive cell is in the dark. But as soon as light shines on the photocell, the voltage-divider output voltage will drop, thereby triggering the comparator and turning off the transistor, the relay, and the light bulb. By adjusting the reference or set point voltage with potentiometer R_3, the triggering point can be varied, so that the light will be turned off or on at the desired level of ambient lighting.

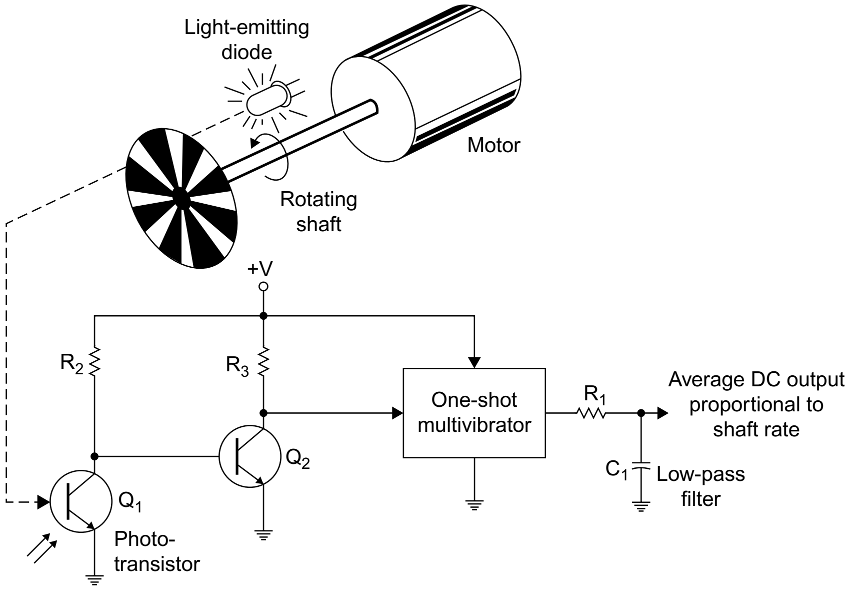

FIGURE 12.12 Simple tachometer circuit using phototransistor to create pulses that are averaged into a DC voltage proportional to speed.

This same basic concept can be used to produce a variety of industrial control operations. For example, you could use the circuit as an entry or intrusion detector. Shine a light on the photocell. If someone or something comes between the light and photocell, the circuit will trigger and the relay could then be used to operate a bell or buzzer or light.

Another example of a photoelectric controller is a tachometer circuit used for measuring the speed of a rotating shaft. Figure 12.12 shows a small, plastic wheel connected to the shaft of a motor. There are alternate clear and opaque areas on the disk. The disk is positioned so that it is between the light-emitting diode (LED) and the phototransistor. As the disk rotates, the dark opaque areas will block the light, while the clear areas pass the light from the LED to the phototransistor. When a clear area on the disk passes, the LED light will shine through it, hitting the phototransistor, and turning it on. When a dark area passes, the light will be blocked and the phototransistor will turn off. The rapidly rotating disk will cause the transistors to turn off and on very rapidly. This rapid conduction and nonconduction of the phototransistor causes a series of pulses to occur at the output of Q_2. These pulses are used to trigger the one-shot multivibrator.

The one-shot multivibrator produces a series of fixed, amplitude-width pulses. These are applied to an RC low-pass filter made up of C_1 and R_1. This filter will average the pulses into a DC voltage. This output voltage is proportional to the motor speed. If the speed of the motor should increase, the pulses occur at a more rapid rate. This means that the pulses occur closer together, and thus the average voltage across C_1 goes up. A DC voltmeter connected to the output can be used to indicate the speed. At low speeds, the meter indication will be low, while at high speeds it will be high. The meter dial itself can be calibrated in terms of revolutions per minute (rpm), thereby giving an accurate speed indication.

Flow Sensors

These devices have liquid or gas pass through them and measure the amount of flow in gallons per minute or other measure. They develop an output voltage proportional to flow rate.

There too many other sensors to catalog here but in most cases there is a sensor to convert any physical variable into a voltage to be measured.

OUTPUT DEVICES

An output device or an *actuator* is the thing that is most often controlled in a control system. The two most common types of actuators are relays and motors. There are many types of both.

Relays

A relay is an electromagnetically operated switch. A typical relay, and its schematic symbol, is illustrated in Figure 12.13. Its main components are a magnetic coil and a set of switching contacts. With no current applied to the coil, the spring keeps the armature pulled down, so that the contact arm makes connection with the upper, normally closed (NC) contact. When current is applied to the coil, a magnetic field is produced. This magnetic field attracts the steel armature, opening the upper contact, and closing the lower, normally open (NO) contact. The contacts form a single-pole, double-throw (SPDT) switch. When power is disconnected from the coil, the magnetic field ceases, and the contacts return to their initial state because of the spring.

Relay coils are designed to be operated from either AC or DC. The contacts are small circular disks of silver or tungsten. These materials are chosen because they will handle a large amount of current with minimum burning, arcing, and pitting.

The various kinds of switching contacts used in relays are illustrated in Figure 12.14. Normally open (NO) contacts are referred to as *form A*. Applying power to the coil closes the contacts. Normally closed (NC) contacts are referred to as *form B*. When power is applied to the relay coil, the contacts open. Single-pole, double-throw switching contacts are referred to as *form C*. When power is applied to the relay coil, the contact arm moves from contact A to contact B. Form C contacts are usually of the break-before-make variety. That is, contact A opens before the arm touches or “makes” contact B.

Sometimes you will hear the expression that a relay has been "picked" or "picked up." This means that power has been applied to the relay coil, and its contacts have been moved according to their function, and switching of a circuit has occurred.

Most relays usually have more than one set of contacts, so that multiple switching operations can be performed simultaneously. The various contact arms are ganged together so that they operate together when power is applied to the coil. A common configuration is two form-A contacts ganged to form a double-pole, single-throw (DPST) relay. Putting two form-C contacts together on the same relay produces a double-pole, double-throw (DPDT) relay.

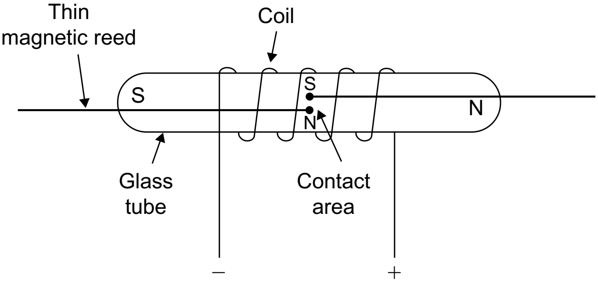

FIGURE 12.15 Reed relay.

Another widely used type of relay is the *reed relay*, illustrated in Figure 12.15. The heart of the reed relay is a reed switch that consists of two thin, metallic, reed contacts sealed in a glass tube. The reed contacts are made of a magnetic material, so that they will be magnetized when a magnetic field is applied to them. A coil consisting of many turns of fine wire is wound on a form and placed over the reed switch. When power is applied to the coil, a magnetic field is produced. This magnetic field magnetizes the two reeds as if they were bar magnets. One end of each reed will have a north pole and a south pole. The reeds are positioned so that the north pole of one will attract the south pole of the other. Remember, magnetic theory says that unlike poles attract, while like poles repel. The result is that the contacts will move toward one another and touch, making a good electrical connection. When power is removed from the coil, the contacts become demagnetized and spring apart. The reed relay will also operate by moving a permanent magnet near it. When the magnet is near, the contacts will close. This is a common way to sense open windows or doors in a home security system.

The contacts on reed relays cannot handle as much power as the contacts on conventional relays because they are smaller. As a result, they are used only in lower current power applications. However, the contacts on a reed relay open and close faster than those of a larger standard relay. Reed relay contacts can open and close in a few hundred microseconds, while standard relays require many milliseconds to open or close because of the larger contacts and the related structures that must be moved.

Relays are used in two basic ways in industrial control:

1. To control a larger current with a smaller current.
2. For remote control.

Let's examine the use of a relay for controlling a larger current with a smaller current. A good example of this is the starting system in your car. A large, heavy-duty DC motor is used to spin the flywheel on the car's engine to start it. This motor draws a current of hundreds of amperes. To turn the engine and start the car, the battery must be connected to the starter motor. This could be done directly by having the ignition switch connect the battery to the motor. However, this switch would have to have very large contacts to handle the high current. Such a switch would be large and expensive to build. The large heavy wires from the battery to the motor would have to be lengthened and brought up into the car.

A better solution is to use a smaller ignition switch to control the current applied to a relay coil (see Figure 12.16). The relay coil draws considerably less current than the motor; therefore, the switch contacts need not be large

or expensive. The switching contacts on the relay are much larger and will carry the high motor current. When the ignition switch is turned, its contacts close, applying current to the relay coil. The form-A contacts close, connecting the battery to the starting motor. When the car starts, the ignition switch is released, the relay drops out, and the starter motor shuts off.

Another application of a relay is remote control. Again, the starting system of a car is a good example. The load to be controlled, in this case the starter motor, is located remotely from the ignition switch. If the ignition switch were used to apply current to the motor, long wires would be required to connect the battery, the motor, and the switch. Heavy wire conductors would have to be used to carry the high current. The longer the interconnecting wires, the higher the resistance of the circuit. While large conductors have minimum resistance, when high current flows through them, voltage drops still occur. The voltage dropped across the interconnecting lines subtract from the battery voltage available for the motor. The voltage drops might be excessive, unless very large, expensive, and inconvenient conductors are used.

To eliminate this problem, a remote relay is used. The relay itself is located near the starter motor and the battery. In this way, the interconnecting leads can be kept short, thereby minimizing voltage drops. Since the relay operates from very low current, longer interconnecting wires can be used to attach it to the ignition switch without noticeable voltage drops.

In some industrial control applications, the load to be operated is located at extreme distances from the switch used to control it. The current controlling the device does not have to be passed through very long conductors if a relay is used. Small conductors running to the switch remotely from the load control the relay while the relay turns the load off and on.

Relay contacts stay closed (or open) as long as power is applied to the coil. This means that the switch operating the relay coil must be kept closed if the relay is to remain actuated. There are applications, however, where it is desirable to use a momentary contact switch to operate the relay. An example is a pushbutton that, when depressed, causes contacts to be closed and power to be applied to the relay. When the button is released, a spring causes the contacts to open. With such an arrangement, the relay will close momentarily while the button is depressed, but will drop out when the button is released. The objective is to cause the relay to latch into its actuated position when the coil is momentarily pulsed. Such a relay is called a *latching relay*. Some latching relays use a mechanical arrangement on the armature to cause the contacts to latch closed when the coil is momentarily pulsed.

A relay can be made to latch electrically if it has an extra set of contacts. A typical latching circuit is shown in Figure 12.17. This relay has two sets of form-C contacts that operate simultaneously. The lower set of contacts is used to operate the load. The upper set of contacts is used to automatically latch the relay once it is pulsed. Switch S_1 is a normally open (NO) momentary contact pushbutton that is used to apply power to the relay coil. Depressing the button

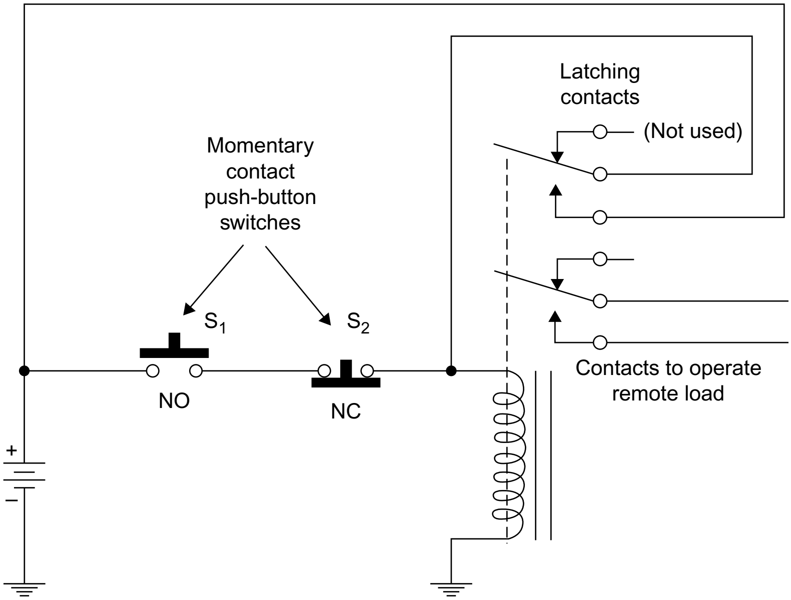

FIGURE 12.17 Latching a relay with its own contacts.

causes the relay coil to operate, closing the contacts. The lower set of contacts operates the load as desired. The upper set of contacts applies the power to the coil. Thus, when pushbutton S_1 is released, the circuit to the relay coil remains closed through the upper-latching contacts. To turn off the circuit, normally closed (NC) pushbutton S_2 must be depressed. This breaks the relay coil circuit, removing power. The relay drops out, opening the load contacts and the latching contacts.

While many relay coils are operated by mechanical switches, others are operated by a transistor. A typical transistor-controlled relay circuit is shown in Figure 12.18. The transistor is operated as a switch. When the base is grounded through contact B on S_1, the transistor is cut off and acts as an open switch. Therefore, no current flows in the relay coil. When a voltage is applied to the base resistor, through contact A on S_1, the transistor saturates, acting like a very-low-resistance or "on" switch. Current flows through the relay coil, operating the contacts. Removing the base current from the transistor turns the transistor off, terminating current in the relay. With this arrangement, an even smaller current can be used to control the already small relay current. A base current, of only microamperes, is sufficient to cause the transistor to operate.

In the circuit of Figure 12.18, when base current is removed from the transistor, the transistor will cut off. When current through the relay coil ceases, the magnetic field around it collapses. In doing so, the magnetic field induces a very high voltage in the relay coil. This very high voltage will be applied to the collector of the transistor. This voltage could be as high as several hundred, or

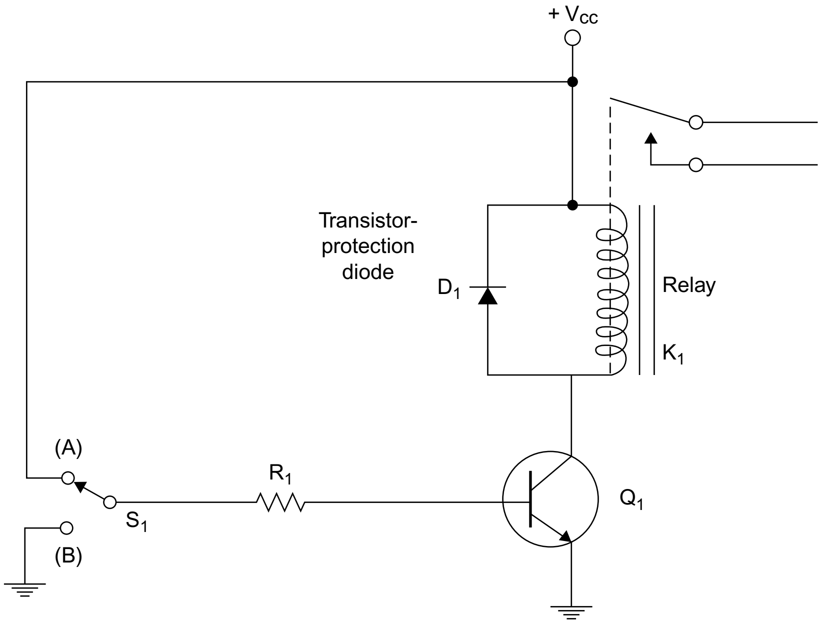

FIGURE 12.18 Operating a relay with a transistor is a common application. The diode protects the transistor when power is removed from the relay coil.

even thousands, of volts, depending on the relay coil. Such a high voltage will damage the transistor. To protect the transistor against such occurrences, some kind of voltage-spike eliminator or surge suppressor must be used across the relay coil. A commonly used protection device is a silicon diode D_1, as shown in Figure 12.18. When current is applied to the relay coil through the transistor, the diode is reverse biased and has absolutely no effect on the circuit. When the transistor turns off, the high voltage will be inducted into the coil with the polarity reversed from the supply voltage V_{cc}. This causes the diode to become forward biased and conduct. Thus, the diode effectively shorts out the high voltage spike, protecting the transistor.

Solenoids

A solenoid is a device that produces linear motion with an electromagnetic coil (see Figure 12.19). A magnetized steel rod called a plunger is inserted into a coil of wire. When a voltage is applied to the coil, a magnetic field is produced. It interacts with the magnetic rod producing attraction and/or repulsion that causes the rod to move into or out of the coil. The rod is usually physically constrained in one or both directions, and is often spring loaded so that it always returns to the same place when power is removed.

Solenoids produce linear motion. They are usually connected to a lever or ratchet mechanism that produces other forms of motion including rotation.

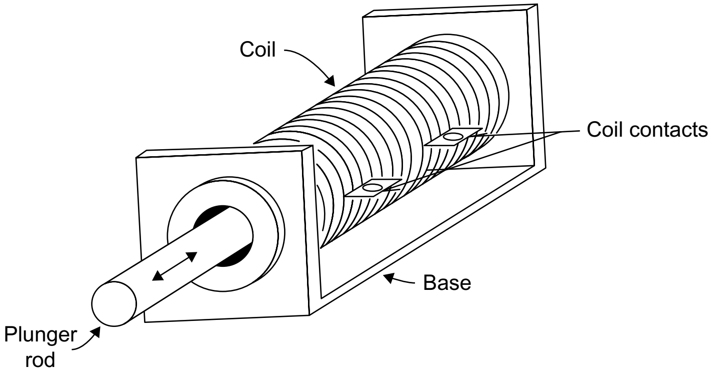

FIGURE 12.19 A solenoid produces linear motion using magnetic principles.

Solenoids are also used in valves to turn off the flow of a liquid or gas. By continuously controlling the current in the coil, the rod may also be precisely set to some position other than off or on. This effect is used in valves to continuously control the opening.

Motors

A motor is a device that converts electrical energy to mechanical energy. The mechanical output is typically the rotation of a shaft. That rotation can then be used directly or converted into other mechanical forms with levers, gears, ratchets, or cams. There are dozens of different motor types but most are categorized as either DC or AC.

Motors: Billions and Billions Sold and Used

Motors are one of those devices we take for granted. We use them every day but don't realize it. Most motors are hidden but do an enormous amount of physical manipulation. In industry, motors drive machine tools, conveyer belts, pumps, and other mechanical systems. Elevators use big motors.

At home motors are everywhere. Just think a minute and try to identify all the motors you have in your home and in your car. All of your appliances have motors, such as the washer, dryer, dishwasher, and HVAC units. There are motors in your mixers, blenders, and can openers. Shavers and hair dryers have motors. An analog clock is a motor. Then there are the motors in your electronics. In a PC or laptop, there are the fan motor and the ones in your hard disk and CD drives. Your printer, scanner, and copier and fax machine have motors. Your DVD player, CD player, and VCR all have multiple motors.

Then in your car is the starter motor, as well as the motors for windows, seats, mirrors, and windshield wipers.

Can you name some others?

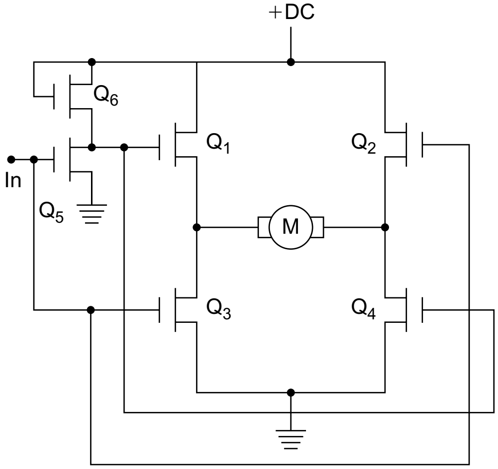

FIGURE 12.20 Using an H-bridge circuit to reverse the current flow and direction of rotation in a DC motor.

DC Motors

A DC motor operates from a DC voltage source like a battery or power supply. It is made up of a magnet and a rotating coil. When a current is applied to the coil, it forms an electromagnet. The magnetism of the coil interacts with the magnet field, producing rotary motion. The magnet is commonly a permanent magnet in smaller DC motors but an electromagnet in larger motors. In the larger motors, a special field coil is energized with DC voltage as well to create the magnetic field.

The main specifications of a motor are its horsepower rating, speed, and torque. Speed and torque are controlled by the amount of current flowing in the coil and/or the strength of the magnetic field. Increasing the voltage applied to the motor usually causes speed and torque to increase. Some kind of electronic control circuit is usually involved to set the speed to the desired value. A variable resistor in series with the motor will control its speed, but usually more complex electronic circuits are involved.

Incidentally, the direction of rotation is determined by the polarity of the DC voltage. Reversing the polarity reverses the magnetic field, thus changing the direction of rotation. Figure 12.20 shows a neat circuit used to change the direction of rotation of a DC motor. This is called an H-bridge and is made up of MOSFET switches. Q_2 and Q_3 are turned on by a positive input voltage IN. Q_5 inverts this voltage to zero, which keeps Q_1 and Q_4 off. Therefore, current (electrons) flows from ground through Q_3 through the motor (M) from left to right through Q_2. Setting the input to zero turns off Q_2 and Q_3 and turns on Q_1 and Q_4. Now current flows from ground through Q_4 and the motor from right to left and then through Q_1. This changes the direction of the motor with just a simple off/off input control voltage.

Most DC motors rotate too fast for many applications. A typical speed range is 1000 to 10,000 rpm. To achieve lower speeds, the motor is used in conjunction with a gear box or pulleys.

A special type of DC motor is the *stepper motor*. This is a DC motor driven by two DC pulse signals. The pulses operate coils or windings that produce a rotating magnetic field. A permanent magnet rotor interacts with the rotating magnetic field to produce motion. The interesting characteristic is that the rotation occurs in increments or steps instead of a continuous rotation as with a standard DC motor. Depending on the number of windings and coils and elements on the rotor, the increments usually vary in increments of 22.5, 18, 15, 7.5, or 3 degrees or smaller. The stepper motor therefore permits very precise positioning. Yet it can be rotated at several thousand rpm if needed.

AC Motors

AC motors usually operate from a 50- or 60-Hz power line. Again the rotation is produced by interacting magnetic fields. The speed of rotation is fixed by the number of coils and magnet poles inside the motor. That speed is also often higher than needed, so gears and/or pulleys are used to drop the speed to the desired value.

To change the speed of an AC motor, you must vary the frequency of the AC voltage applied to it. This means that you cannot operate the motor directly from the AC power line if the speed must be changed. Instead, you must use a so-called AC drive. This is a box of electronics that generates a variable frequency AC voltage to apply to the motor. An AC drive takes the AC line input and uses semiconductor switches to produce an AC signal at a different frequency.

Other Actuators

Besides motors, solenoids, and relays, there are a variety of different controlled devices. Valves are common device. Valves are used to turn the flow of a liquid or gas on or off. Proportional valves very carefully regulate the amount of flow.

Other devices are hydraulic or pneumatic devices. Hydraulic devices use oil in cylinders to provide mechanical force where needed or position something mechanically. Pneumatic cylinders work with compressed air to apply force or control the position of a device.

THYRISTORS

Many industrial switching circuits are implemented with MOSFETs designed for high voltage and high power. You will sometimes hear these devices called *insulated gate field-effect transistors* (IGFETs).

Other power-switching devices are also widely used, especially thyristors. A thyristor is a semiconductor device used for switching purposes in industrial control. Like the relay, it is used to apply and control electrical power to motors, heating elements, lights, and other loads in industrial applications. In many applications, thyristors replace relays. A thyristor acts as a switch, but because of its solid-state nature, is far faster in switching than a relay. There are three basic types of thyristors: silicon-controlled rectifiers (SCRs), triacs, and diacs.

Silicon-Controlled Rectifier

The SCR is a three-terminal thyristor that acts like a silicon rectifier diode whose conductor is controlled by an input current. The schematic symbol for an SCR is shown in Figure 12.21. The symbol is similar to that of a diode with a cathode and an anode. Note that the third element of the SCR is known as the gate. The SCR will conduct current between cathode and anode, but only if the proper control current is applied to the gate. The gate must be made positive with respect to the cathode in order for the SCR to conduct. When conducting, the SCR acts like a closed switch. The voltage drop across the cathode and anode will be approximately 0.7 to 1.8 volts, depending on the size of the SCR and how much current is flowing through it. When the cathode and anode are reverse biased, current will not flow through the device.

Thyristors, like relays, are generally used to control a larger current with a smaller current. Figure 12.22 shows how an SCR is used as a switch to apply DC power to a light bulb. The load could also be a motor or heating element. The DC voltage is connected so that the cathode and anode of the SCR are forward biased, but no current will flow through the device until a current is applied to the gate. This is done with the switch S_1. With the switch open, no current flows in the gate. Closing the switch, however, applies a positive voltage to the gate through resistor R_1. This causes the SCR to turn on. When it conducts, it acts as a low-resistance "on" switch and the light bulb goes on. At this point, switch S_1 may be opened. It is not necessary to maintain current in the gate in order for the device to continue to conduct. The gate current only

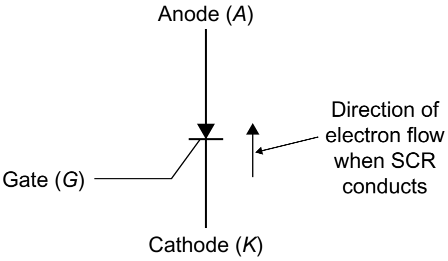

FIGURE 12.21 Schematic symbol of an SCR.

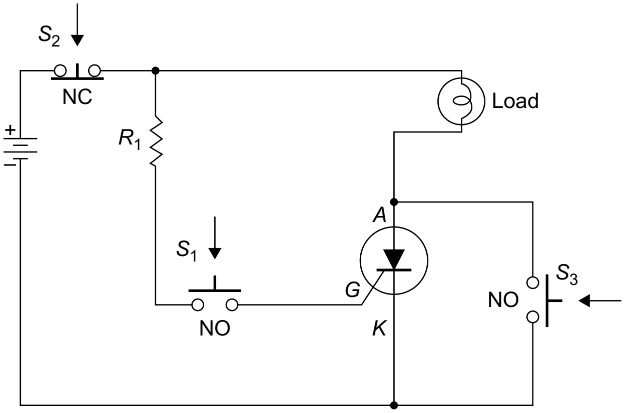

FIGURE 12.22 Circuit that shows how an SCR is turned on and off.

needs to be momentary, for it is only required to turn the device on. The device remains on like a latching relay that has been pulsed.

The gate element is only used to turn the SCR on. Removing gate current will not turn the device off. To cause the SCR to stop conducting, the circuit must be broken. This can be done with a momentary-contact, normally closed pushbutton, in series with the circuit, like S_2 in Figure 12.22. Depressing this pushbutton will break the circuit, stopping the current in the SCR, and the light bulb will go off. To turn the bulb back on, S_1 must again be depressed to apply gate current momentarily.

Another way to stop conduction is to momentarily short around the SCR, as shown in Figure 12.15. When switch S_3 is closed momentarily, current will flow through it and the bulb, bypassing the SCR. The current in the SCR will drop to zero. When switch S_3 is opened, the circuit will be off.

While SCRs are sometimes used to control DC power, in most applications they are used to control AC. Figure 12.23A shows the SCR used to apply AC to a light bulb. If switch S_1 is closed, gate current will be applied to the device. The device, however, will only conduct when the anode is made positive with respect to the cathode. This, of course, occurs when the applied AC voltage has the correct polarity. Since the SCR operates as a rectifier diode, current will only flow through the device on the positive half-cycles of the sine wave. The current through the light bulb will be a pulsating DC, as illustrated in Figure 12.23B. The brightness of the lamp will depend on the average amount of current flowing.

The average amount of current through the light bulb, or other load, can be controlled by using the gate element. Various electronic circuits are used to adjust the time when the SCR turns on. By turning on the SCR at the appropriate time in the positive half-cycle, the duration of the current flow can be controlled. The longer the current is allowed to flow, the higher the average

current in the load. By changing the control point, the brightness of the bulb can be varied.

Diac

A diac is a two-terminal semiconductor device that conducts in either direction when a voltage of a specific level is exceeded. This voltage is called the *triggering voltage*. Typical diac triggering voltages are in the 20- to 45-volt range. The diac is used as a triggering device for SCR and triacs as it determines when the device will conduct or cut off.

Triac

A triac is another three-terminal thyristor. Its operation is similar to that of an SCR, but the triac will conduct in either direction. The schematic symbol for the triac is shown in Figure 12.24. Current will flow from main terminal 1 (MT1)

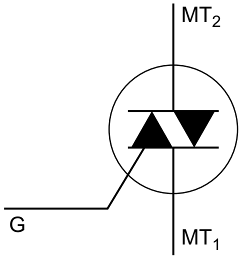

FIGURE 12.24 Schematic symbol for triac.

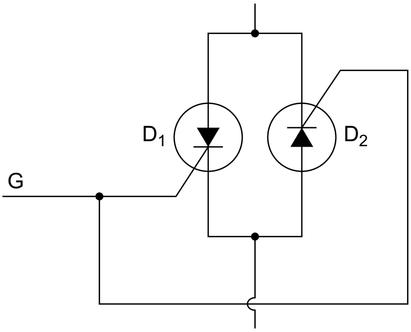

FIGURE 12.25 Equivalent circuit of triac shown with SCRs.

to main terminal 2 (MT2), or from main terminal 2 (MT2) to main terminal 1 (MT1), depending on the polarity of the voltage applied, and if the gate triggers the device on.

An approximate, equivalent circuit of the triac is shown in Figure 12.25. Here, two SCRs are connected back to back with their gates connected together. Current can flow in either direction, depending on whether D_1 or D_2 conducts. Of course, SCR conduction depends on whether a gate-triggering current is applied. Triacs, like SCRs, are used primarily to switch AC voltage to a load. If gate current is applied continuously, the triac will conduct in both forward and backward directions, causing both positive and negative half-cycles of the AC to be applied to a load.

Figure 12.26 shows a circuit used for light-dimming purposes. The load is a light bulb. An RC phase shifter and diac-triggering device are used on the gate of the triac. Assume that the diac has a triggering voltage of 30 volts. If the voltage across the diac is less than 30 volts, it will not conduct. As soon as the 30-volt point is reached or exceeded, the diac rapidly conducts and fires the SCR. Keep in mind that the diac is a bidirectional device, and that current will flow through it in either direction if the bias voltage in either direction exceeds the triggering voltage level.

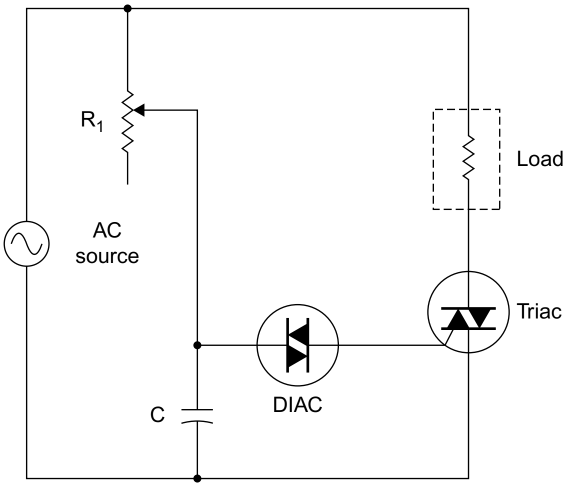

FIGURE 12.26 Lamp dimmer circuit using RC phase shifter and diac to control current in the load.

The triac will conduct on both positive and negative half-cycles of the applied AC. The phase shifter made up of R_1 and C will set the triggering delay. It will determine at what point in the AC cycle the diac will fire and apply gate current to the triac. Figure 12.27 shows the waveforms at two different phase-shift points in the circuit. Note that current flows through the load in both the positive and negative half-cycles, but the duration of current flow depends on the point where the gate triggers. In Figure 12.27, the average current through the load will be relatively high at a 60-degree phase shift, and the bulb will be bright. At 120 degrees, the triggering point is late in each half-cycle, allowing only a small amount of current to flow through the bulb. The bulb, therefore, will glow dimly. Adjusting R_1 will allow the brightness of the bulb to be varied from nearly full on to full off. This is the circuit normally used in household and industrial light dimmers.

This same circuit can be used to control the speed of AC motors. In connecting a hand drill as the load, for example, R_1 will vary the speed of rotation.

Triacs are also widely used as solid-state relays.

PROGRAMMABLE LOGIC CONTROLLERS

A very popular type of controller used in industry and process control is a specialized computer called a programmable logic controller (PLC), or programmable controller. It uses sensors to monitor physical variables and generates output control signals to operate heating elements, motors, pumps, solenoids, and other devices. The PLC, however, contains a microprocessor that can be

programmed in a special language that permits the PLC to be customized to the particular control function. In this way, a standard PLC can be programmed and configured for virtually any application. The PLC is by far one of the most popular and versatile control devices in use in industry.

The main function of a PLC is factory automation. It is a versatile special-purpose computer that can be quickly and easily reconfigured to meet changes

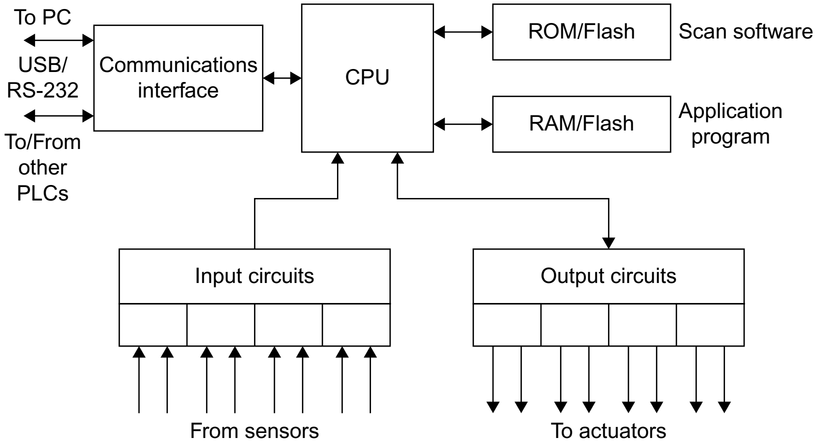

FIGURE 12.28 General block diagram of PLC.

and additions in factories, plants, and other operations that routinely need to control and sequence various machines and processes. While an embedded controller or personal computer could be used in some operations, they are harder to program and apply and are less flexible when rapid changes are needed. Furthermore, these common microcomputers are not designed for the factory environment. But PLCs are rugged and hardened against the harsh environment of most factories and plants. They can withstand the temperature ranges, vibration, and dirty conditions usually existing in a manufacturing or process control setting.

Organization

A general block diagram of a PLC is shown in Figure 12.28. It is like most other microcomputer diagrams but there are some differences. A microprocessor is at the heart of the design. This CPU is coupled to a ROM where a special control program is stored. This program implements the basic scan operational mode of the PLC. RAM is also available to store the application program. Flash memory may also be used in place of RAM.

The key to the PLC's versatility is its extensive I/O section. It has a variety of input and output modules. These are fixed in small, single-function PLCs, but in the larger more flexible units, the PLC is designed to accept a wide variety of separate I/O modules. These usually plug into a rack containing the main PLC unit and power supply. The different I/O modules let the user customize the PLC to the specific application.

Some examples of I/O modules are digital inputs and outputs with common logic levels or conditioned levels, analog-input modules that accept analog signals from sensors, and analog output modules that generate analog outputs for controlling actuators of almost any kind. A huge variety is available.

A communications interface is also available so that the PLC can talk to external devices like a PC or other PLCs that are connected to form a larger control system. RS-232 and RS-485 serial interfaces are common as is USB. The program describing the operations to be implemented is developed on an external PC, and then downloaded to the PLC RAM or flash memory via the USB or RS-232 interfaces.

Operation

The general operation of a PLC is shown in Figure 12.29. When the PLC is started, the internal operational program looks at the application program and interprets what is to be done. The sequence of operations is to first scan the inputs. The PLC looks at what the various sensors are doing. It gets a status update from the application itself. The program then interprets what to do next based on the application program. It processes the input to determine what the outputs should be. Then it updates the outputs to carry out the application. Then the cycle repeats itself at a high rate of speed. The inputs are scanned and outputs updated every 1 millisecond or so, slower or faster as the application requires.

A simple example is using a switch to turn on a motor. The switch contacts are connected to an input module by wires. Output wires connect to a relay that in turn is used to operate the motor. As the PLC is scanning, it sees that the switch is off, so it does nothing. But as soon as the switch is turned

FIGURE 12.29 PLC operational scan cycle.

on, the next scan detects this new condition. The program then tells the CPU that if the switch is on, turn on the relay. An output signal is sent to the output module, which then actuates an external relay. The relay contacts then turn the motor on. If the switch is then turned off, the next scan detects this condition and causes the output to turn off the relay and motor.

Programming

As for programming, PLCs can be programmed in various ways. Most PLC vendors have special languages to do the programming. In some cases, standard BASIC or C languages may be used. One widely used approach is a graphical language called *ladder logic*. Ladder logic is the technology that the PLC replaced decades ago. Control systems were made with relays, and they were wired so the diagram looked like a ladder (see Figure 12.30). The two vertical lines represent a DC or AC voltage source. Circuits are then connected between these two "rails," forming rungs on the ladder. The circuits are connections of switches, relays, and other components. The software allows the user to build the ladder logic program on the screen, while a translation program in the PC converts it into the binary code that the PLC can execute.

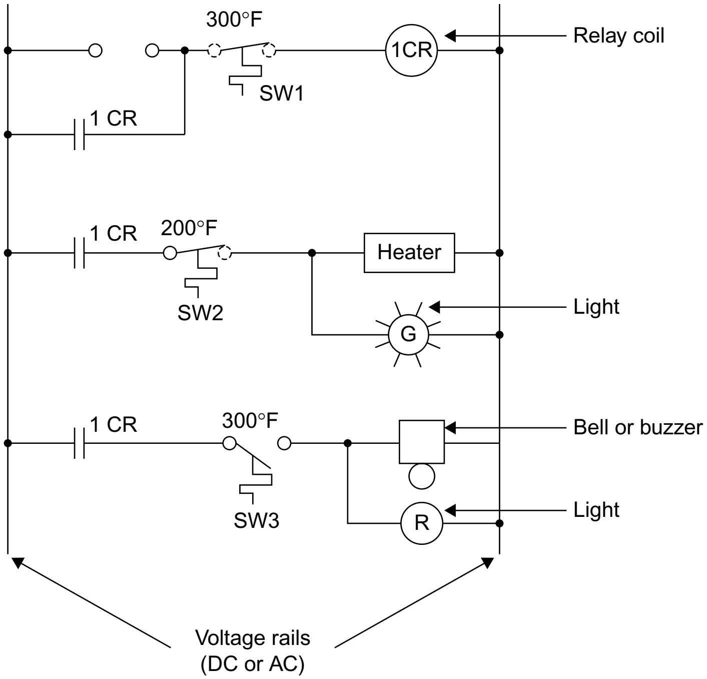

FIGURE 12.30 Sample ladder diagram and PLC application program.

This particular circuit in Figure 12.30 does the following: when the ON pushbutton is pressed, current is applied to relay coil 1CR through normally closed contacts of SW1. SW1 is a thermal switch whose contacts stay closed as long as the temperature is less than 300 degrees Fahrenheit (300°F). If the temperature rises above that level, the contacts open, thereby breaking the circuits. Relay contacts 1CR around the ON pushbutton latch the circuit on when the ON pushbutton is released.

In the next "rung" of the ladder contacts 1CR are on the relay. They close when the relay turns on. This applies voltage to a heating element. This current flows through the normally closed contacts of thermal switch SW2. A green light in parallel with the heating elements turns on to indicate the heater is on.

When the heater temperature reaches 200°F, SW2 opens, turning off the heater and the green light. As the heater cools, SW2 will then close again, applying voltage to the heater. The heater will then cycle off and on keeping its temperature near the 200°F value.

If the temperature should rise above 300°F due to a failure of SW2 °F then SW1 opens. Relay 1CR is turned off, and its contacts open, releasing the latch on rung 1 and opening the circuit on rung 2. Thermal switch SW3 closes at 300°F, turning on a red light and ringing an alarm bell.

This example could be programmed with a graphical ladder logic program or with special commands and syntax of a traditional programming language.

In addition to being able do simple off/off tasks common to industrial control, special hardware in the PLC can also implement counters and timers so that external events can be counted and the sequencing of events can be programmed.

Build a Robot

Robots are great examples of basic industrial control. While most industrial robots are usually manipulator arms, you can actually buy a mobile robot with wheels that can be programmed for motion and other functions. A wide range of kits are available. It is a great way to get familiar with sensors, a microcomputer controller, and various actuators. Typical inputs are switches, photo cells, temperature sensors, and common outputs are relays, lights, and motors.

Some recommended kits are those made by Lego and Parallax. Suggested websites to learn more follow:

Lego Mindstorms NXT: www.mindstorms.lego.com

Parallax: www.parallax.com

Two magazines regularly cover robots from a hobbyist/experimenter viewpoint. These are *Nuts & Volts* and *Servo*. You may be able to find these at a newsstand; otherwise, go to their websites:

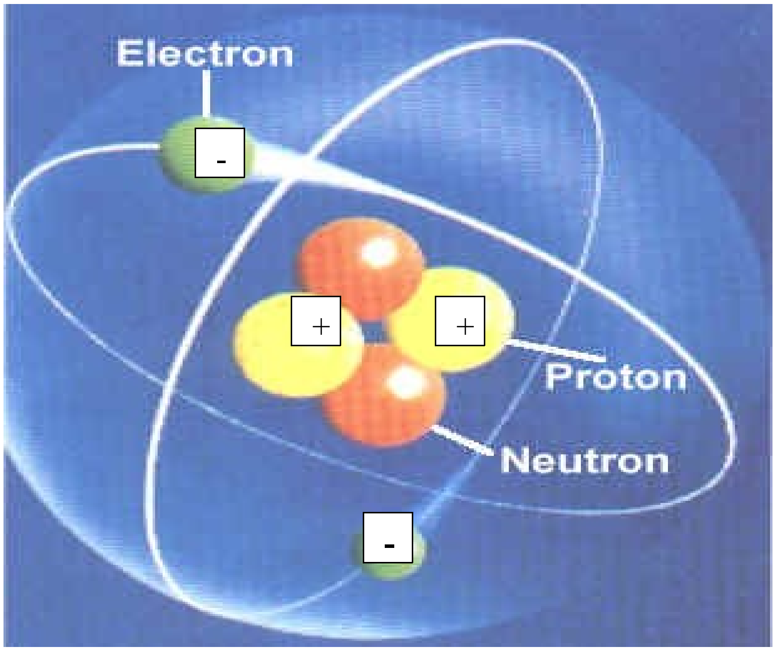
Atom



The **atom** is a basic unit of matter consisting of a dense, central nucleus surrounded by a cloud of negatively charged electrons. The atomic nucleus contains a mix of positively charged protons and electrically neutral neutrons (except in the case of Hydrogen-1, which is the only stable nuclide with no neutron). The electrons of an atom are bound to the nucleus by the electromagnetic force. Likewise, a group of atoms can remain bound to each other, forming a molecule. An atom containing an equal number of protons and electrons is electrically neutral, otherwise it has a positive or negative charge and is an ion. An atom is classified according to the number of protons and neutrons in its nucleus: the number of protons determines the chemical element, and the number of neutrons determine the isotope of the element.

Electron

The **electron** is a subatomic particle that carries a negative electric charge. It has no known substructure and is believed to be a point particle.[2] Electrons participate in gravitational, electromagnetic and weak interactions. Like its rest mass and elementary charge, the intrinsic angular momentum (or spin) of an electron has a constant value. In the collision of an electron and a positron, the electron's antiparticle, both are annihilated. An electron–positron pair can be produced from gamma ray photons with sufficient energy.

Proton

The **proton** is a subatomic particle with an electric charge of +1 elementary charge. It is found in the nucleus of each atom but is also stable by itself and has a second identity as the hydrogen ion, H^+. It is composed of 3 even more fundamental particles comprising two up quarks and one down quark.

Neutron

The **neutron** is a subatomic particle with no net electric charge and a mass slightly larger than that of a proton.

Neutrons are usually found in atomic nuclei. The nuclei of most atoms consist of protons and neutrons, which are therefore collectively referred to as nucleons. The number of protons in a nucleus is the atomic number and defines the type of element the atom forms. The number of neutrons determines the isotope of an element. For example, the carbon-12 isotope has 6 protons and 6 neutrons, while the carbon-14 isotope has 6 protons and 8 neutrons.

Electrical conductor

In science and engineering, an electrical **conductor** is a material which contains movable electric charges. In metallic conductors, such as copper or aluminum, the movable charged particles are electrons (See electrical conduction). Positive charges may also be mobile in the form of atoms in a lattice missing electrons (called "holes") or ions, such as in the electrolyte of a battery.

Note: The following applies to direct current only. When the direction of voltage/current alternates, other effects (inductive and capacitive reactance) come into play also.

All conductors contain electric charges which will move when an electric potential difference (measured in volts) is applied across separate points on the material. This flow of charge (measured in amperes) is what is meant by *electric current*. In most materials, the rate of current is proportional to the voltage (as determined by Ohm's law) provided the temperature remains constant and the material remains in the same shape and state.

Most familiar conductors are metallic. Copper is the most common material for electrical wiring (silver is the best but expensive), and gold for high-quality surface-to-surface contacts. However, there are also many non-metallic conductors, including graphite, solutions of salts, and all plasmas. See electrical conduction for more information on the physical mechanism for charge flow in materials.

Non-conducting materials lack mobile charges, and so resist the flow of electric current, generating heat. In fact, all non-superconducting materials offer some resistance and warm up when a current flows. Thus, proper design of an electrical conductor takes into account the temperature that the conductor needs to be able to endure without damage, as well as the quantity of electrical current. The motion of charges also creates an electromagnetic field around the conductor that exerts a mechanical radial squeezing force on the conductor. A conductor of a given material and volume (length x cross-sectional area) has no real limit to the current it can carry without being destroyed as long as the heat generated by the resistive loss is removed and the conductor can withstand the radial forces. This effect is especially critical in printed circuits, where conductors are relatively small and close together, and inside an enclosure: the heat produced, if not properly removed, can cause fusing (melting) of the tracks.

Since all non-superconducting conductors have some resistance, and all insulators will carry some current, there is no theoretical dividing line between conductors and insulators. However, there is a large gap between the conductance of materials that will carry a *useful current* at working voltages and those that will carry a negligible current for the purpose in hand, so the categories of *insulator* and *conductor* do have practical utility.

Thermal and electrical conductivity often go together (for instance, most metals are both electrical and thermal conductors). However, some materials are practical electrical conductors without being a good thermal conductor.

(Electrical) Non Conductor (Insulator)

An **insulator**, also called a *dielectric*, is a material that resists the flow of electric current. An insulating material has atoms with tightly bonded valence electrons. These materials are used in parts of electrical equipment, also called *insulators* or *insulation*, intended to support or separate electrical conductors without passing current through themselves. The term is also used more specifically to refer to insulating supports that attach electric power transmission wires to utility poles or pylons.

Some materials such as glass or Teflon are very good electrical insulators. A much larger class of materials, for example rubber-like polymers and most plastics are still "good enough" to insulate electrical wiring and cables even though they may have lower bulk resistivity. These materials can serve as practical and safe insulators for low to moderate voltages (hundreds, or even thousands, of volts).

Semiconductor

A **semiconductor** is a material that has electrical conductivity between those of a conductor and an insulator. The conductivity of a semiconductor material can be varied under an external electrical field. Devices made from semiconductor materials are the foundation of modern electronics, including radio, computers, telephones, and many other devices. Semiconductor devices include the transistor, many kinds of diodes including the light-emitting diode, the silicon controlled rectifier, and digital and analog integrated circuits. Solar photovoltaic panels are large semiconductor devices that directly convert light energy into electrical energy.

In a metallic conductor, current is carried by the flow of electrons. In semiconductors, current can be carried either by the flow of electrons or by the flow of positively-charged "holes" in the electron structure of the material.

Silicon is used to create most semiconductors commercially. Dozens of other materials are used, including germanium, gallium arsenide, and silicon carbide. A pure semiconductor is often called an “intrinsic” semiconductor. The conductivity, or ability to conduct, of semiconductor material can be drastically changed by adding other elements, called “impurities” to the melted intrinsic material and then allowing the melt to solidify into a new and different crystal. This process is called "doping".

CURRENT:

The flow of Electron through a conductor is called current. The no. of electronics moving through a conductor per second called Ampere.

The unit of current is **“Ampere”.**

Sub Unit:

nA = Nano Ampere = 10^{-9} = 1/1000000000
µA = Micro Ampere = 10^{-6} = 1-1000000
mA = Milli Ampere = 10^{-3} = 1/1000
A = Ampere = 1
KA = Kilo Ampere = 10^{3} = 1000
MA = Mega Ampere = 10^{6} = 1000000
GA = Giga Ampere = 10^{9} = 1000000000

current Conversion:

1000 nA = 1 µA

1000 µ A = 1 mA

1000 mA = 1 A

1000 A = 1 KA

1000 KA = 1 MA

1000 MA = 1 GA

Types of Current:
There are two types 1. AC Current
2. DC Current

AC – Current & DC - Current

Alternating Current (AC)

Alternating Current (AC) flows one way, then the other way, continually reversing direction.

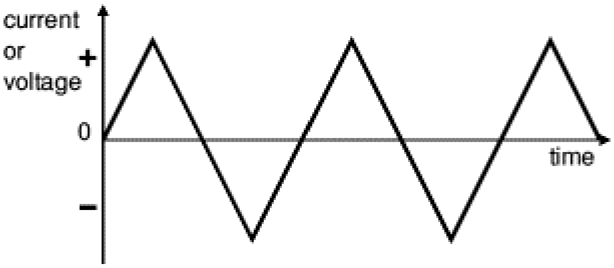
An AC voltage is continually changing between positive (+) and negative (-).

The rate of changing direction is called the **frequency** of the AC and it is measured in **hertz (Hz)** which is the number of forwards-backwards **cycles per second**.

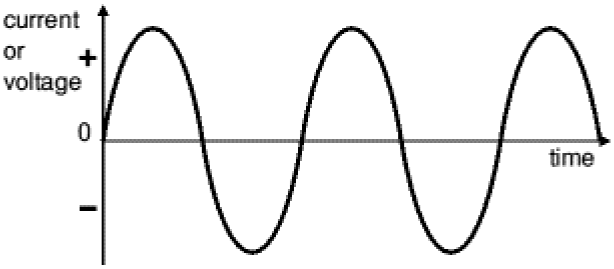
Mains electricity in the UK has a frequency of 50Hz.

See below for more details of signal properties.

An AC supply is suitable for powering some devices such as lamps and heaters but almost all electronic circuits require a steady DC supply (see below).



This triangular signal is AC because it changes between positive (+) and negative (-).



AC from a power supply
This shape is called a **sine wave**.

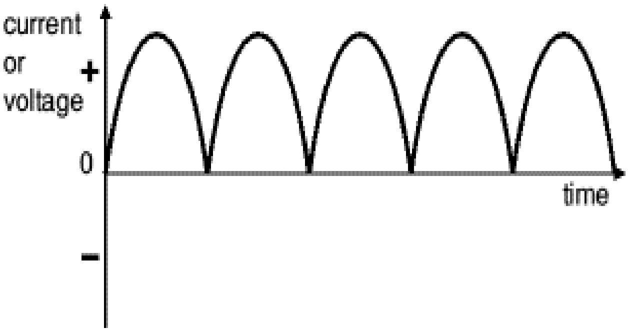
Direct Current (DC)

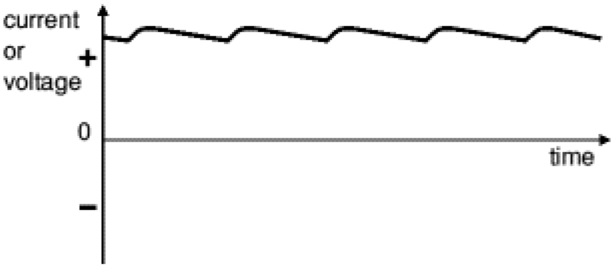
Direct Current (DC) always flows in the same direction, but it may increase and decrease.

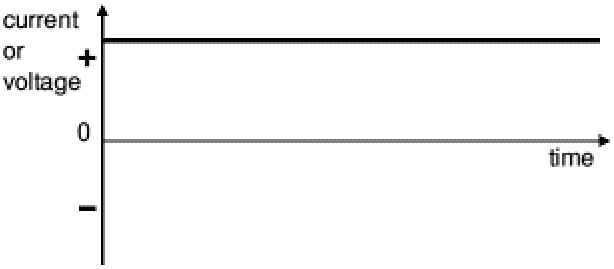
A DC voltage is always positive (or always negative), but it may increase and decrease.

Electronic circuits normally require a **steady DC** supply which is constant at one value or a **smooth DC** supply which has a small variation called **ripple**.

Cells, batteries and regulated power supplies provide **steady DC** which is ideal for electronic circuits.







Power supplies contain a transformer which converts the mains AC supply to a safe low voltage AC. Then the AC is converted to DC by a bridge rectifier but the output is **varying DC** which is unsuitable for electronic circuits.

Some power supplies include a capacitor to provide **smooth DC** which is suitable for less-sensitive electronic circuits, including most of the projects on this website.

Lamps, heaters and motors will work with any DC supply.

Voltage

What is voltage?

Voltage is a measure of the electric force available to cause the movement or flow of electrons. Thus, voltage in itself implies no movement of electrons, but the potential to cause electrons to move.

Voltage measurements of direct current

When an electric force is available to cause the movement of electrons, a voltmeter is used to measure the potential. When that potential is unchanging, it is said to be a direct current or DC potential. DC electricity typically comes from a battery, but may come from a filtered, rectified power supply. More on rectification and filtering later.

Voltage measurements of alternating current

When an electrical force is available to cause the movement of electrons, it can sometimes not be measured accurately because the value is changing instant-by-instant. In a typical generator, for example, it can be changing in value between -110Volts and +110 volts in a sinusoidal (sine wave) fashion. Voltage that changes instant-by-instant, such as your household power, is called AC or Alternating Current.

In these cases, a rectified value is extracted and filtered in order that an average, 'positive' voltage value can be measured. More on the mechanism of rectification later but know that this is a method of converting AC into DC electricity.

Voltage:

The difference of Electric potential which exists between two points of conduction carrying a constant of one Ampere. When the power dissipate between these points in one watt.

The unit of Voltage **"Volt" = V**

nV = Nano Volt = 10^{-9} = 1/1000000000
µV = Micro Volt = 10^{-6} = 1-1000000
mV = Milli Volt = 10^{-3} = 1/1000
V = Volt = 1
KV = Kilo Volt = 10^{3} = 1000
MV = Mega Volt = 10^{6} = 1000000
GV = Giga Volt = 10^{9} = 1000000000

Current Conversion:

1000 nV = 1 µV

1000 µ V = 1 mV

1000mV = 1 V

1000 V = 1 KV

1000 KV = 1 MV

1000 MV = 1 GV

There are two types of Voltage

AC Voltage & DC Voltage.

Electric power

Electric power is defined as the rate at which electrical energy is transferred by an electric circuit. The SI unit of power is the watt.

When electric current flows in a circuit, it can transfer energy to do mechanical or thermodynamic work. Devices convert electrical energy into many useful forms, such as heat (electric heaters), light (light bulbs), motion (electric motors), sound (loudspeaker) or chemical changes. Electricity can be produced mechanically by generation, or chemically, or by direct conversion from light in photovoltaic cells, also it can be stored chemically in batteries.

The electric power in watts associated with a complete electric circuit or a circuit component represents the rate at which energy is converted from the electrical energy of the moving charges to some other form, e.g., heat, mechanical energy, or energy stored in electric fields or magnetic fields. For a resistor in a D C Circuit the power is given by the product of applied voltage and the electric current:

P = VI

Power = Voltage x Current

☐ Watts = ☐ volts x ☐ amperes

Enter data in any two of the boxes, then click on the active text for the quantity you wish to calculate.

Ohm's law

$$\frac{V}{I * R}$$

V = I*R
I = V/R
R =V/I

Ohm's law applies to electrical circuits; it states that the current through a conductor between two points is directly proportional to the potential difference or voltage across the two points, and inversely proportional to the resistance between them.

The mathematical equation that describes this relationship is:

Where I is the current in amperes, V is the potential difference in volts, and R is a circuit parameter called the resistance (measured in ohms, also equivalent to volts per ampere). The potential difference is also known as the voltage drop, and is sometimes denoted by U, E or emf (electromotive force) instead of V.

The law was named after the German physicist Georg Ohm, who, in a treatise published in 1827, described measurements of applied voltage and current through simple electrical circuits containing various lengths of wire. He presented a slightly more complex equation than the one above to explain his experimental results. The above equation is the modern form of Ohm's law.

The resistance of most resistive devices (resistors) is constant over a large range of values of current and voltage. When a resistor is used under these conditions, the resistor is referred to as an *ohmic device* (or an *ohmic resistor*) because a single value for the resistance suffices to describe the resistive behavior of the device over the range. When sufficiently high voltages are applied to a resistor, forcing a high current through it, the device is no longer ohmic because its resistance, when measured under such electrically stressed conditions, is different (typically greater) from the value measured under standard conditions (see temperature effects, below).

Ohm's law, in the form above, is an extremely useful equation in the field of electrical/electronic engineering because it describes how voltage, current and resistance are interrelated on a "macroscopic" level, that is, commonly, as circuit elements in an electrical circuit. Physicists who study the electrical properties of matter at the microscopic level use a closely related and more general vector equation, sometimes also referred to as Ohm's law, having variables that are closely related to the I, V and R scalar variables of Ohm's law, but are each functions of position within the conductor. See the Physics and Relation to heat conduction sections below.

Electrical circuits consist of electrical devices connected by wires (or other suitable conductors). (See the article electrical circuits for some basic combinations.) The above diagram shows one of the simplest electrical circuits that can be constructed. One electrical device is shown as a circle with + and - terminals, which represents a voltage source such as a battery. The other device is illustrated by a zig-zag symbol and has an R beside it. This symbol represents a resistor, and the R designates its resistance. The + or positive terminal of the voltage source is connected to one of the terminals of the resistor using a wire of negligible resistance, and through this wire a current I is shown, in a specified direction illustrated by the arrow. The other terminal of the resistor is connected to the - or negative terminal of the voltage source by a second wire. This configuration forms a complete circuit because all the current that leaves one terminal of the voltage source must return to the other terminal of the voltage source. (While not shown, because electrical engineers assume that it exists, there is an implied current I, and an arrow pointing to the left, associated with the second wire.)

Voltage is the electrical driver that moves (negatively charged) electrons through wires and electrical devices, current is the rate of electron flow, and resistance is the property of a resistor (or other device that obeys Ohm's law) that limits current to an amount proportional to the applied voltage. So, for a given resistance R (ohms),

and a given voltage V (volts) established across the resistance, Ohm's law provides the equation (I=V/R) for calculating the current through the resistor (or device).

The "conductor" mentioned by Ohm's law is a circuit element across which the voltage is measured. Resistors are conductors that slow down the passage of electric charge. A resistor with a high value of resistance, say greater than 10 megohms, is a poor conductor, while a resistor with a low value, say less than 0.1 ohm, is a good conductor. (Insulators are materials that, for most practical purposes, do not allow a current when a voltage is applied.)

In a circuit diagram, like the one above, the various components may be joined by connectors, contacts, welds or solder joints of various kinds, but for simplicity these connections are usually not shown.

Electronic Symbols

Wires and connections

Component	Circuit Symbol	Function of Component
Wire		To pass current very easily from one part of a circuit to another.
Wires joined		A 'blob' should be drawn where wires are connected (joined), but it is sometimes omitted. Wires connected at 'crossroads' should be staggered slightly to form two T-junctions, as shown on the right.
Wires not joined		In complex diagrams it is often necessary to draw wires crossing even though they are not connected. I prefer the 'bridge' symbol shown on the right because the simple crossing on the left may be misread as a join where you have forgotten to add a 'blob'!

Power Supplies

Component	Circuit Symbol	Function of Component
Cell		Supplies electrical energy. The larger terminal (on the left) is positive (+). A single cell is often called a battery, but strictly a battery is two or more cells joined together.
Battery		Supplies electrical energy. A battery is more than one cell. The larger terminal (on the left) is positive (+).
DC supply		Supplies electrical energy. DC = Direct Current, always flowing in one direction.
AC supply		Supplies electrical energy. AC = Alternating Current, continually changing direction.
Fuse		A safety device which will 'blow' (melt) if the current flowing through it exceeds a specified value.
Transformer		Two coils of wire linked by an iron core. Transformers are used to step up (increase) and step down (decrease) AC voltages. Energy is transferred between the coils by the magnetic field in the core. There is no electrical connection between the coils.

Earth (Ground)		A connection to earth. For many electronic circuits this is the 0V (zero volts) of the power supply, but for mains electricity and some radio circuits it really means the earth. It is also known as ground.

Output Devices: Lamps, Heater, Motor, etc.

Component	**Circuit Symbol**	**Function of Component**
Lamp (lighting)		A transducer which converts electrical energy to light. This symbol is used for a lamp providing illumination, for example a car headlamp or torch bulb.
Lamp (indicator)		A transducer which converts electrical energy to light. This symbol is used for a lamp which is an indicator, for example a warning light on a car dashboard.
Heater		A transducer which converts electrical energy to heat.
Motor		A transducer which converts electrical energy to kinetic energy (motion).
Bell		A transducer which converts electrical energy to sound.
Buzzer		A transducer which converts electrical energy to sound.
Inductor (Coil, Solenoid)		A coil of wire which creates a magnetic field when current passes through it. It may have an iron core inside the coil. It can be used as a transducer converting electrical energy to mechanical energy by pulling on something.

Switches

Component	**Circuit Symbol**	**Function of Component**
Push Switch (push-to-make)		A push switch allows current to flow only when the button is pressed. This is the switch used to operate a doorbell.
Push-to-Break Switch		This type of push switch is normally closed (on), it is open (off) only when the button is pressed.
On-Off Switch (SPST)		SPST = Single Pole, Single Throw. An on-off switch allows current to flow only when it is in the closed (on) position.
2-way Switch (SPDT)		SPDT = Single Pole, Double Throw. A 2-way changeover switch directs the flow of current to one of two routes according to its position. Some SPDT switches have a central off position and are described as 'on-off-on'.

Dual On-Off Switch (DPST)		DPST = Double Pole, Single Throw. A dual on-off switch which is often used to switch mains electricity because it can isolate both the live and neutral connections.
Reversing Switch (DPDT)		DPDT = Double Pole, Double Throw. This switch can be wired up as a reversing switch for a motor. Some DPDT switches have a central off position.
Relay		An electrically operated switch, for example a 9V battery circuit connected to the coil can switch a 230V AC mains circuit. NO = Normally Open, COM = Common, NC = Normally Closed.

Resistors

Component	**Circuit Symbol**	**Function of Component**
Resistor		A resistor restricts the flow of current, for example to limit the current passing through an LED. A resistor is used with a capacitor in a timing circuit. Some publications still use the old resistor symbol: Variable Resistor (Rheostat)		This type of variable resistor with 2 contacts (a rheostat) is usually used to control current. Examples include: adjusting lamp brightness, adjusting motor speed, and adjusting the rate of flow of charge into a capacitor in a timing circuit.
Variable Resistor (Potentiometer)		This type of variable resistor with 3 contacts (a potentiometer) is usually used to control voltage. It can be used like this as a transducer converting position (angle of the control spindle) to an electrical signal.
Variable Resistor (Preset)		This type of variable resistor (a preset) is operated with a small screwdriver or similar tool. It is designed to be set when the circuit is made and then left without further adjustment. Presets are cheaper

		than normal variable resistors so they are often used in projects to reduce the cost.

Capacitors

Component	Circuit Symbol	Function of Component
Capacitor		A capacitor stores electric charge. A capacitor is used with a resistor in a timing circuit. It can also be used as a filter, to block DC signals but pass AC signals.
Capacitor, polarised		A capacitor stores electric charge. This type must be connected the correct way round. A capacitor is used with a resistor in a timing circuit. It can also be used as a filter, to block DC signals but pass AC signals.
Variable Capacitor		A variable capacitor is used in a radio tuner.
Trimmer Capacitor		This type of variable capacitor (a trimmer) is operated with a small screwdriver or similar tool. It is designed to be set when the circuit is made and then left without further adjustment.

Diodes

Component	Circuit Symbol	Function of Component
Diode		A device which only allows current to flow in one direction.
LED Light Emitting Diode		A transducer which converts electrical energy to light.
Zener Diode		A special diode which is used to maintain a fixed voltage across its terminals.
Photodiode		A light-sensitive diode.

Transistors

Component	Circuit Symbol	Function of Component
Transistor NPN		A transistor amplifies current. It can be used with other components to make an amplifier or switching circuit.
Transistor PNP		A transistor amplifies current. It can be used with other components to make an amplifier or switching circuit.
Phototransistor		A light-sensitive transistor.

Audio and Radio Devices

Component	Circuit Symbol	Function of Component
Microphone		A transducer which converts sound to electrical energy.
Earphone		A transducer which converts electrical energy to sound.
Loudspeaker		A transducer which converts electrical energy to sound.
Piezo Transducer		A transducer which converts electrical energy to sound.
Amplifier (general symbol)		An amplifier circuit with one input. Really it is a block diagram symbol because it represents a circuit rather than just one component.

Aerial (Antenna)		A device which is designed to receive or transmit radio signals. It is also known as an antenna.

Meters and Oscilloscope

Component	Circuit Symbol	Function of Component
Voltmeter		A voltmeter is used to measure voltage. The proper name for voltage is 'potential difference', but most people prefer to say voltage!
Ammeter		An ammeter is used to measure current.
Galvanometer		A galvanometer is a very sensitive meter which is used to measure tiny currents, usually 1mA or less.
Ohmmeter		An ohmmeter is used to measure resistance. Most multimeters have an ohmmeter setting.
Oscilloscope		An oscilloscope is used to display the shape of electrical signals and it can be used to measure their voltage and time period.

Sensors (input devices)

Component	Circuit Symbol	Function of Component
LDR		A transducer which converts brightness (light) to resistance (an electrical property). LDR = Light Dependent Resistor
Thermistor		A transducer which converts temperature (heat) to resistance (an electrical property).

Logic Gates

Logic gates process signals which represent **true** (1, high, +Vs, on) or **false** (0, low, 0V, off). For more information please see the Logic Gates page. There are two sets of symbols: traditional and IEC (International Electrotechnical Commission).

Gate Type	Traditional Symbol	IEC Symbol	Function of Gate
NOT			A NOT gate can only have one input. The 'o' on the output means 'not'. The output of a NOT gate is the inverse (opposite) of its input, so the output is true when the input is false. A NOT gate is also called an inverter.
AND			An AND gate can have two or more inputs. The output of an AND gate is true when all its inputs are true.
NAND			A NAND gate can have two or more inputs. The 'o' on the output means 'not' showing that it is a Not AND gate. The output of a NAND gate is true unless all its inputs are true.
OR			An OR gate can have two or more inputs. The output of an OR gate is true when at least one of its inputs is true.
NOR			A NOR gate can have two or more inputs. The 'o' on the output means 'not' showing that it is a Not OR gate. The output of a NOR gate is true when none of its inputs are true.
EX-OR			An EX-OR gate can only have two inputs. The output of an EX-OR gate is true when its inputs are different (one true, one false).
EX-NOR			An EX-NOR gate can only have two inputs. The 'o' on the output means 'not' showing that it is a Not EX-OR gate. The output of an EX-NOR gate is true when its inputs are the same (both true or both false).

Multimeters

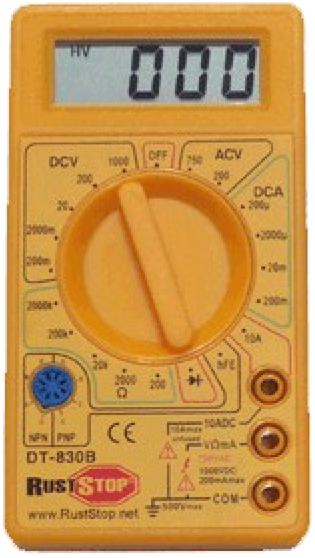
Multimeters are very useful test instruments. By operating a multi-position switch on the meter they can be quickly and easily set to be a voltmeter, an ammeter or an ohmmeter. They have several settings (called 'ranges') for each type of meter and the choice of AC or DC. Some multimeters have additional features such as transistor testing and ranges for measuring capacitance and frequency.

Choosing a multimeter

The photographs below show modestly priced multimeters which are suitable for general electronics use, you should be able to buy meters like these for less than £15. A digital multimeter is the best choice for your first multimeter; even the cheapest will be suitable for testing simple projects.

If you are buying an analogue multimeter make sure it has a high sensitivity of 20k/V or greater on DC voltage ranges, anything less is not suitable for electronics. The sensitivity is normally marked in a corner of the scale, ignore the lower AC value (sensitivity on AC ranges is less important), the higher DC value is the critical one. Beware of cheap analogue multimeters sold for electrical work on cars because their sensitivity is likely to be too low.

Digital multimeters



All digital meters contain a battery to power the display so they use virtually no power from the circuit under test. This means that on their DC voltage ranges they have a very high resistance (usually called input impedance) of 1M or more, usually 10M, and they are very unlikely to affect the circuit under test.

Typical ranges for digital multimeters like the one illustrated:

(The values given are the maximum reading on each range)

DC Voltage: 200mV, 2000mV, 20V, 200V, 600V.

AC Voltage: 200V, 600V.

DC Current: 200µA, 2000µA, 20mA, 200mA, 10A*.

*The 10A range is usually unfused and connected via a special socket.

AC Current: None. (You are unlikely to need to measure this).

Resistance: 200 ohms, 2000 ohms, 20k ohms, 200k ohms, 2000k ohms, Diode Test.

Digital meters have a special diode test setting because their resistance ranges cannot be used to test diodes and other semiconductors.

Analogue multimeters

Analogue meters take a little power from the circuit under test to operate their pointer. They must have a high sensitivity of at least 20k/V or they may upset the circuit under test and give an incorrect reading. See the section below on sensitivity for more details.

Batteries inside the meter provide power for the resistance ranges, they will last several years but you should avoid leaving the meter set to a resistance range in case the leads touch accidentally and run the battery flat.

Typical ranges for analogue multimeters like the one illustrated:

(The voltage and current values given are the maximum reading on each range)

DC Voltage: 0.5V, 2.5V, 10V, 50V, 250V, 1000V.

AC Voltage: 10V, 50V, 250V, 1000V.

DC Current: 50µA, 2.5mA, 25mA, 250mA.

PHOTOGRAPHERS
DIRECT.COM

A high current range is often missing from this type of meter.

AC Current: None. (You are unlikely to need to measure this).

Resistance: 20 ohms, 200 ohms, 2k ohms, 20k ohms, 200k ohms.

These resistance values are in the middle of the scale for each range.

It is a good idea to leave an analogue multimeter set to a DC voltage range such as 10V when not in use. It is less likely to be damaged by careless use on this range, and there is a good chance that it will be the range you need to use next anyway!

Sensitivity of an analogue multimeter

Multimeters must have a high sensitivity of at least 20k/V otherwise their resistance on DC voltage ranges may be too low to avoid upsetting the circuit under test and giving an incorrect reading. To obtain valid readings the meter resistance should be at least 10 times the circuit resistance (take this to be the highest resistor value near where the meter is connected). You can increase the meter resistance by selecting a higher voltage range, but this may give a reading which is too small to read accurately!

On any DC voltage range:

Analogue Meter Resistance = Sensitivity × Max. reading of range

e.g. a meter with 20k/V sensitivity on its 10V range has a resistance of 20k/V × 10V = 200k.

By contrast, digital multimeters have a constant resistance of at least 1M ohms (often 10M ohms) on all their DC voltage ranges. This is more than enough for almost all circuits.

RESISTORS

A **Resistor** is a two-terminal electronic component designed to oppose an electric current by producing a voltage drop between its terminals in proportion to the current, that is, in accordance with Ohm's law:

$$V = IR$$

Resistors are used as part of electrical networks and electronic circuits. They are extremely commonplace in most electronic equipment. Practical resistors can be made of various compounds and films, as well as resistance wire (wire made of a high-resistivity alloy, such as nickel/chrome).

The primary characteristics of resistors are their resistance and the power they can dissipate. Other characteristics include temperature coefficient, noise, and inductance. Less well-known is critical resistance, the value below which power dissipation limits the maximum permitted current flow, and above which the limit is applied voltage. Critical resistance depends upon the materials constituting the resistor as well as its physical dimensions; it's determined by design.

Resistors can be integrated into hybrid and printed circuits, as well as integrated circuits. Size, and position of leads (or terminals) are relevant to equipment designers; resistors must be physically large enough not to overheat when dissipating their power.

Units

The **ohm** (symbol: Ω) is a SI-driven unit of electrical resistance, named after Georg Simon Ohm. Commonly used multiples and submultiples in electrical and electronic usage are the milliohm, kilohm, and megohm.

Examples	
R47	0.47 ohms
4R7	4.7 ohms
470R	470 ohms
4K7	4.7K ohms
47K	47K ohms
47K3	47.3K ohms

470K	470K ohms
4M7	4.7M ohms

The unit of Resistor is **“OHMS”.**

Sub Unit:

nΩ = Nano OHMS = 10^{-9} = 1/1000000000
µΩ = Micro OHMS = 10^{-6} = 1-1000000
mΩ = Milli OHMS = 10^{-3} = 1/1000
A = OHMS = 1
KΩ = Kilo OHMS = 10^{3} = 1000
MΩ = Mega OHMS = 10^{6} = 1000000
GΩ = Giga OHMS = 10^{9} = 1000000000

Resistor Conversion:

1000 nΩ = 1 µΩ

1000 µ Ω = 1 mΩ

1000 mΩ = 1 Ω

1000 Ω = 1 KΩ

1000 KΩ = 1 MΩ

1000 MΩ = 1 GΩ

Carbon film

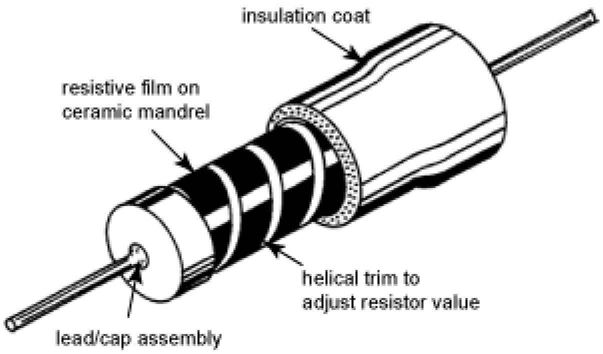
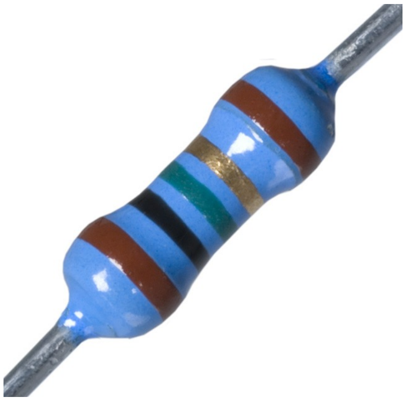
ceramic rod

A carbon film is deposited on an insulating substrate, and a helix cut in it to create a long, narrow resistive path. Varying shapes, coupled with the resistivity of carbon, (ranging from 9 to 40 µΩ-cm) can provide a variety of resistances.[1] Carbon film resistors feature a power rating range of 1/6 W to 5 W at 70°C. Resistances available range from 1 ohm to 10 megohm. The carbon film resistor can operate between temperatures of -55°C to 155°C. It has 200 to 600 volts maximum working voltage range

Metal film



insulation coat
resistive film on ceramic mandrel
helical trim to adjust resistor value
lead/cap assembly



A common type of axial resistor today is referred to as a metal-film resistor. MELF (Metal Electrode Leadless Face) resistors often use the same technology, but are a cylindrically shaped resistor designed for surface mounting. [Note that other types of resistors, e.g. carbon composition, are also available in "MELF" packages].

Metal film resistors are usually coated with nickel chromium (NiCr), but might be coated with any of the cermet materials listed above for thin film resistors. Unlike thin film resistors, the material may be applied using different techniques than sputtering (though that is one such technique). Also, unlike thin-film resistors, the resistance value is determined by cutting a helix through the coating rather than by etching. [This is similar to the way carbon resistors are made.] The result is a reasonable tolerance (0.5, 1, or 2%) and a temperature coefficient of (usually) 25 or 50 ppm/K.

Wire wound

Wire wound resistors are commonly made by winding a metal wire around a ceramic, plastic, or fiberglass core. The ends of the wire are soldered or welded to two caps, attached to the ends of the core. The assembly is protected with a layer of paint, molded plastic, or an enamel coating baked at high temperature. The wire leads are usually between 0.6 and 0.8 mm in diameter and tinned for ease of soldering. For higher power wire wound resistors, either a ceramic outer case or an aluminum outer case on top of an insulating layer is used. The aluminum-cased types are designed to be attached to a heat sink to dissipate the heat; the rated power is dependent on being used with a suitable heat sink, e.g., a 50 W power rated resistor will overheat at around one fifth of the power dissipation if not used with a heat sink.

Actual lengths will vary

Because wire wound resistors are coils they have more undesirable inductance than other types of resistor, although winding the wire in sections with alternately reversed direction can minimize inductance.

Cermet

A **cer met** is a composite material composed of ceramic (cer) and metallic (met) materials. A cer met is ideally designed to have the optimal properties of both a ceramic, such as high temperature resistance and hardness, and those of a metal, such as the ability to undergo plastic deformation. The metal is used as a binder for an oxide, boride, carbide, or alumina. Generally, the metallic elements used are nickel, molybdenum, and cobalt. Depending on the physical structure of the material, cermets can also be metal matrix composites, but cermets are usually less than 20% metal by volume.

Cermets are used in the manufacture of resistors (especially potentiometers), capacitors, and other electronic components which may experience high temperatures.

Cermets are being used instead of tungsten carbide in saws and other brazed tools due to their superior wear and corrosion properties. TiCN, TiC, TiN and similar can be brazed like tungsten carbide if properly prepared however they require special handling during grinding.

More complex materials, known as Cermet 2 or Cermet II, are being utilized since they give considerably longer life in cutting tools while both brazing and grinding like tungsten carbide.

Some types of cermets are also being considered for use as spacecraft shielding as they resist the high velocity impacts of micrometeoroids and orbital debris much more effectively than more traditional spacecraft materials such as aluminum and other metals.

Measurement

Nearly always, the resistance value is of interest. The value of a resistor can be measured with an ohmmeter, which may be one function of a multimeter. Usually, probes on the ends of test leads connect to the resistor.

Measuring low-value resistors, such as fractional-ohm resistors, with acceptable accuracy requires four-terminal connections. One pair of terminals applies a known, calibrated current to the resistor, while the other pair senses the voltage drop across the resistor. Some laboratory test instruments have spring-loaded pairs of contacts, with neighboring contacts electrically isolated from each other. Better digital multimeters have four terminals on their panels, generally used with special test leads. These comprise four wires in all, and have special test clips with jaws insulated from each other. One jaw provides the measuring current, while the other senses the voltage drop.

Series and parallel resistors

Main article: Series and parallel circuits

Resistors in a parallel configuration each have the same potential difference (voltage). To find their total equivalent resistance (R_{eq}):

$$1/R = 1/R1 + 1/R2 + \ldots.. + 1/Rn$$

The parallel property can be represented in equations by two vertical lines "||" (as in geometry) to simplify equations. For two resistors,

$R = R1 // R2 = R1,R2 / R1 + R2$

The current through resistors in series stays the same, but the voltage across each resistor can be different. The sum of the potential differences (voltage) is equal to the total voltage. To find their total resistance:

$$R = R1 + R2 \ldots..+ Rn$$

A resistor network that is a combination of parallel and series can sometimes be broken up into smaller parts that are either one or the other. For instance,

However, many resistor networks cannot be split up in this way. Consider a cube, each edge of which has been replaced by a resistor. For example, determining the resistance between two opposite vertices requires matrix methods for the general case. However, if all twelve resistors are equal, the corner-to-corner resistance is ⅚ of any one of them.

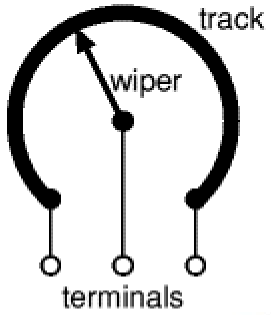
The practical application to resistors is that a resistance of any non-standard value can be obtained by connecting standard values in series or in parallel.

Fixed and Variable Resistors

There are two kinds of resistors, FIXED and VARIABLE. The fixed resistor will have one value and will never change (other than through temperature, age, etc.). The resistors shown in A and B of figure 1-29are classed as fixed resistors. The tapped resistor illustrated in B has several fixed taps and makes more than one resistance value available. The sliding contact resistor shown in C has an adjustable collar that can be moved to tap off any resistance within the ohmic value range of the resistor.

There are two types of variable resistors, one called a POTENTIOMETER and the other a RHEOSTAT (see views D and E of fig. 1-29.)An example of the potentiometer is the volume control on your radio, and an example of the rheostat is the dimmer control for the dash lights in an automobile. There is a slight difference between them. Rheostats usually have two connections, one fixed and the other moveable. Any variable resistor can properly be called a rheostat. The potentiometer always has three connections, two fixed and one moveable. Generally, the rheostat has a limited range of values and a high current-handling capability. The potentiometer has a wide range of values, but it usually has a limited current-handling capability. Potentiometers are always connected as voltage dividers.

Construction



Standard Variable Resistor

Variable resistors consist of a resistance **track** with connections at both ends and a **wiper** which moves along the track as you turn the spindle. The track may be made from carbon, cer met (ceramic and metal mixture) or a coil of wire (for low resistances). The track is usually rotary but straight track versions, usually called sliders, are also available.

Variable resistors may be used as a rheostat with **two** connections (the wiper and just one end of the track) or as a potentiometer with all **three** connections in use. Miniature versions called presets are made for setting up circuits which will not require further adjustment.

Variable resistors are often called **potentiometers** in books and catalogues. They are specified by their maximum resistance, linear or logarithmic track, and their physical size. The standard spindle diameter is 6mm.

The resistance and type of track are marked on the body:

4K7 LIN means 4.7 kΩ linear track.

1M LOG means 1 MΩ logarithmic track.

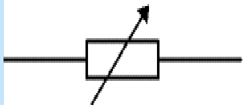
Some variable resistors are designed to be mounted directly on the circuit board, but most are for mounting through a hole drilled in the case containing the circuit with stranded wire connecting their terminals to the circuit board.

Linear (LIN) and Logarithmic (LOG) tracks

Linear (LIN) track means that the resistance changes at a constant rate as you move the wiper. This is the standard arrangement and you should assume this type is required if a project does not specify the type of track. Presets always have linear tracks.

Logarithmic (LOG) track means that the resistance changes slowly at one end of the track and rapidly at the other end, so halfway along the track is **not** half the total resistance! This arrangement is used for volume (loudness) controls because the human ear has a logarithmic response to loudness so fine control (slow change) is required at low volumes and coarser control (rapid change) at high volumes. It is important to connect the ends of the track the correct way round, if you find that turning the spindle increases the volume rapidly followed by little further change you should swap the connections to the ends of the track.

Rheostat



This is the simplest way of using a variable resistor. **Two terminals** are used: one connected to an end of the track, the other to the moveable wiper. Turning the spindle changes the resistance between the two terminals from zero up to the maximum resistance.

Rheostats are often used to **vary current**, for example to control the brightness of a lamp or the rate at which a capacitor charges.

If the rheostat is mounted on a printed circuit board you may find that all three terminals are connected! However, one of them will be linked to the wiper terminal. This improves the mechanical strength of the mounting but it serves no function electrically.

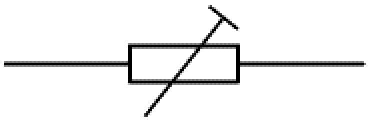
Potentiometer Symbol

Variable resistors used as potentiometers have all **three terminals** connected.

This arrangement is normally used to **vary voltage**, for example to set the switching point of a circuit with a sensor, or control the volume (loudness) in an amplifier circuit. If the terminals at the ends of the track are connected across the power supply

then the wiper terminal will provide a voltage which can be varied from zero up to the maximum of the supply.

Presets



Preset Symbol

These are miniature versions of the standard variable resistor. They are designed to be mounted directly onto the circuit board and adjusted only when the circuit is built. For example to set the frequency of an alarm tone or the sensitivity of a light-sensitive circuit. A small screwdriver or similar tool is required to adjust presets.

Presets are much cheaper than standard variable resistors so they are sometimes used in projects where a standard variable resistor would normally be used.

Multiturn presets are used where very precise adjustments must be made. The screw must be turned many times (10+) to move the slider from one end of the track to the other, giving very fine control.

Four-band resistors

Main article: Electronic color code

Four-band identification is the most commonly used color-coding scheme on all resistors. It consists of four colored bands that are painted around the body of the resistor. The first two bands encode the first two significant digits of the resistance value, the third is a power-of-ten multiplier or number-of-zeroes, and the fourth is the tolerance accuracy, or acceptable error, of the value. Sometimes a fifth band identifies the thermal coefficient, but this must be distinguished from the true 5-color system, with 3 significant digits.

For example, green-blue-yellow-red is $56\times10^4\ \Omega = 560\ \mathrm{k}\Omega \pm 2\%$. An easier description can be as followed: the first band, green, has a value of 5 and the second band, blue, has a value of 6, and is counted as 56. The third band, yellow, has a value of 10^4, which adds four 0's to the end, creating 560,000Ω at ±2% tolerance accuracy. 560,000Ω changes to 560 kΩ ±2% (as a kilo- is 10^3).

Each color corresponds to a certain digit, progressing from darker to lighter colors, as shown in the chart below.

5 band axial resistors

5-band identification is used for higher precision (lower tolerance) resistors (1%, 0.5%, 0.25%, 0.1%), to specify a third significant digit. The first three bands represent the significant digits, the fourth is the multiplier, and the fifth is the tolerance. Five-band resistors with a gold or silver 4th band are sometimes encountered, generally on older or specialized resistors. The 4th band is the tolerance and the 5th the temperature coefficient.

Thermistor

A **thermistor** is a type of resistor whose resistance varies with temperature. The word is a portmanteau of *thermal* and *resistor*. Thermistors are widely used as inrush current limiters, temperature sensors, self-resetting over current protectors, and self-regulating heating elements.

Thermistors differ from resistance temperature detectors (RTD) in that the material used in a thermistor is generally a ceramic or polymer, while RTDs use pure metals. The temperature response is also different; RTDs are useful over larger temperature ranges, while thermistors typically achieve a higher precision within a limited temperature range.

PTC thermistors for over current protection

Ceramic PTC thermistors are used instead of conventional fuses to protect loads such as motors, transformers, etc. or electronic circuits against over current. They not only respond to inadmissibly high currents but also if a preset temperature limit is exceeded. Thermistor fuses limit the power dissipation of the overall circuit by increasing their resistance and thus reducing the current to a harmless residual value. In contrast to conventional fuses, they do not have to be replaced after elimination of the fault but resume their protective function immediately after a short cooling-downtime.

As opposed to PTC thermistors made of plastic materials, ceramic PTC thermistors always return to their initial resistance value, even after frequent heating/cooling cycles.

PTC thermistors as limit temperature sensors

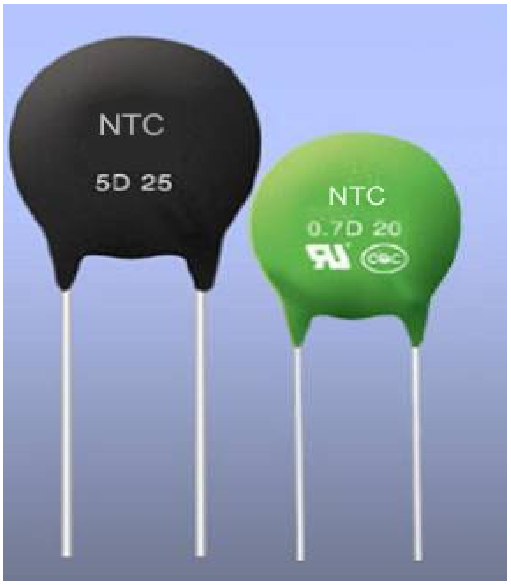
With PTC thermistors as temperature sensors only the steep region of the *R/T* characteristic is Used. The resistance of the PTC thermistor is to be regarded as a function of the ambient temperature [*R*PTC = f (*T*A)].

The precondition for this relationship between resistance and ambient temperature is that self-heating and/or the varistor effect are excluded. This means that these PTC thermistors must be operated in the lowest possible field strengths. To enable a fast response, thermistor sensors have especially small dimensions. High control accuracy is achieved by using materials with an extra steep resistance/temperature characteristic.

Limit temperature measurement for industrial applications

A PTC thermistor can be used effectively to detect whether a temperature limit in industrial equipment, liquids, etc. is exceeded. The PTC thermistor is mounted in thermal contact with the medium that has to be protected from overheating. When the rated temperature limit of the medium is reached, the resistance of the PTC thermistor increases abruptly. In connection with a control unit, this signal can be used to automatically switch off the power supply of a load. EPCOS offers leaded disks, metal tags, screw-type metal cases as well as surface-mounted devices.

NTC thermistors



1. Introduction

An NTC thermistor has to be connected in series to the power source circuit to avoid the surge current at the instant when the electronic circuits are turned on. The device can effectively suppress the surge current, and its resistance and power consumption can be greatly reduced after that through the continuous effect of the current so as not to affect the normal work current. Therefore the Power NTC thermistor is the most convenient and efficient instrument to curb the surge current and protect the electronic devices from being damaged.

2. Applications

Applicable to the protection of the power circuits of conversion power supply, switching power supply, UPS power supply, electric heaters, electronic energy-saving lamps, electronic ballasts and other electronic devices, and the filament protection of color picture tubes, incandescent lamps and other lights.

3. Characteristics:

¡¤Small size, Strong power and strong capability of surge current protection.
¡¤Characteristics Fast response to the rapidly surge.
¡¤Big material constant (B value), Small remain resistance.
¡¤Longevity of service, High reliability.
¡¤Integral series, Extensive operating range.

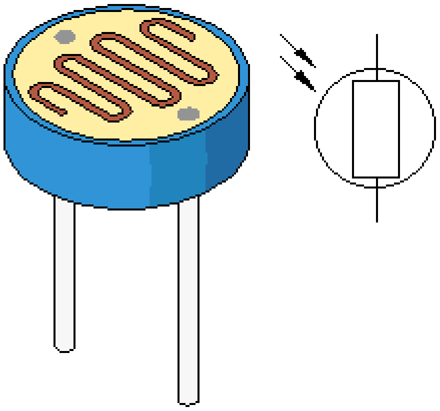
Varistor

Avaristor is an electronic component with a significant non-ohmic current–voltage characteristic. The name is a portmanteau of *variable resistor*. Varistors are often used to protect circuits against excessive transient voltages by incorporating them into the circuit in such a way that, when triggered, they will shunt the current created by the high voltage away from the sensitive components. A varistor is also known as *Voltage Dependent Resistor* or **VDR**. A varistor’s function is to conduct significantly increased current when voltage is excessive.

*Note: only non-ohmic variable resistors are usually called varistors. Other, ohmic types of variable resistor include the potentiometer and the rheostat.

Light Dependent Resistor

A **Light Dependent Resistor** (aka LDR, photoconductor, or photocell) is a device which has a resistance which varies according to the amount of light falling on its surface.



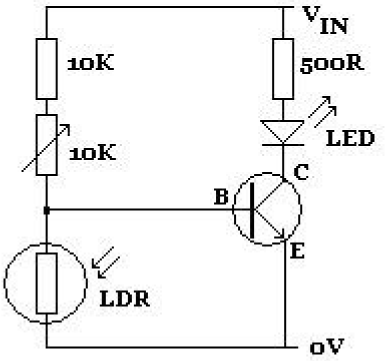
A typical light dependent resistor is pictured above together with (on the right hand side) its circuit diagram symbol. Different LDR's have different specifications, however the **LDR**'s we sell (1) in the REUK Shop (2) are fairly standard and have a resistance in total darkness of 1 MOhm, and a resistance of a couple of kOhm in bright light (*10-20kOhm @ 10 lux, 2-4kOhm @ 100 lux*).

Uses for Light Dependent Resistors

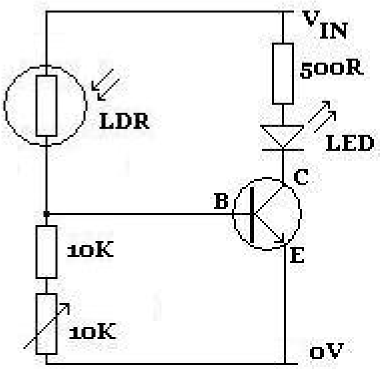
Light dependent resistors are a vital component in any electric circuit (3) which is to be turned on and off automatically according to the level of ambient light - for example, solar powered garden lights, and night security lighting.
An LDR can even be used in a simple remote control circuit using the backlight of a mobile phone to turn on a device - call the mobile from anywhere in the world, it lights up the LDR, and lighting (or a garden sprinkler (4)) can be turned on remotely!

Light Dependent Resistor Circuits

There are two basic circuits using **light dependent resistors** - the first is activated by darkness, the second is activated by light. The two circuits are very similar and just require an **LDR**, some standard resistors (5), a variable resistor (6) (aka potentiometer), and any small signal transistor (7)



In the circuit diagram above, the **LED (8) lights up** whenever the LDR is in **darkness**. The 10K variable resistor is used to fine-tune the level of darkness required before the LED lights up. The 10K standard resistor can be changed as required to achieve the desired effect, although any replacement must be at least **1K** to protect the transistor from being damaged by excessive current.



By swapping the LDR over with the 10K and 10K variable resistors (as shown above), the circuit will be activated instead by light. Whenever sufficient light falls on the LDR (manually fine-tuned using the 10K variable resistor), the LED will light up.

Using an LDR in the Real World

The circuits shown above are not practically useful. In a real world circuit, the LED (and resistor) between the positive voltage input (Vin) and the collector (C) of the transistor would be replaced with the device to be powered.

Typically a **relay** is used - particularly when the low voltage light detecting circuit is used to switch on (or off) a 240V mains powered device. A diagram of that part of the circuit is shown above. When darkness falls (if the LDR circuit is configured that way around), the **relay is triggered** and the 240V device - for example a security light –switches on.

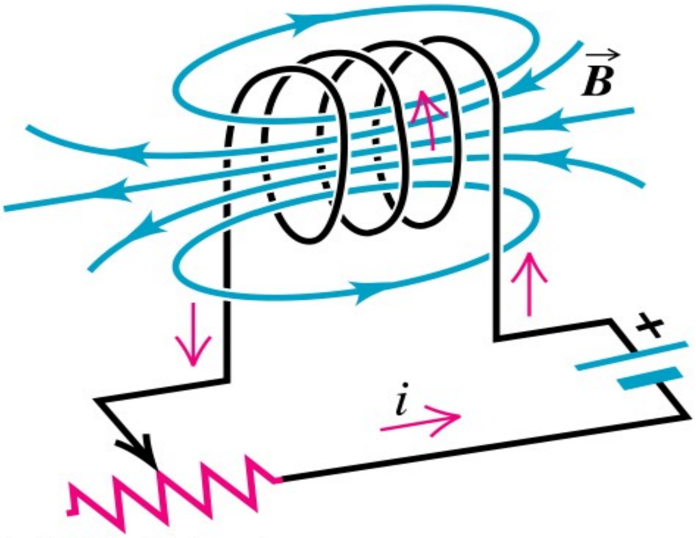
Inductor



Copyright © Addison Wesley Longman, Inc.

An **inductor** or **reactor** is a passive electrical component that can store energy in a magnetic field created by the electric current passing through it. An inductor's ability to store magnetic energy is measured by its inductance, in units of henries. Typically an inductor is a conducting wire shaped as a coil, the loops help create a strong magnetic field inside the coil due to Faraday's law of induction. Inductors are one of the basic electronic components used in electronics where current and voltage change with time, due to the ability of inductors to delay and reshape alternating currents.

Overview

Inductance (*L*) (measured in henries) is an effect resulting from the magnetic field that forms around a current-carrying conductor that tends to resist changes in the current. Electric current through the conductor creates a magnetic flux proportional to the current. A change in this current creates a change in magnetic flux that, in turn, by Faraday's law generates an electromotive force (EMF) that acts to oppose this change in current. Inductance is a measure of the amount of EMF generated for a unit change in current. For example, an inductor with an inductance of 1 henry produces an EMF of 1 volt when the current through the inductor changes at the rate of 1 ampere per second. The number of loops, the size of each loop, and the material it is wrapped around all affect the inductance. For example, the magnetic flux linking these turns can be increased by coiling the conductor around a material with a high permeability such as iron. This can increase the inductance by 2000 times, although less so at high frequencies.

The unit of Inductor is **“Henry”.**

Sub Unit:

nH = Nano **Henry** = 10^{-9} = 1/1000000000
µH = Micro **Henry** = 10^{-6} = 1-1000000
mH = Milli **Henry** = 10^{-3} = 1/1000
H = **Henry** = 1
KH = Kilo **Henry** = 10^{3} = 1000

Inductor Conversion:

1000 nH = 1 µH

1000 µ H = 1 mH

1000 mH = 1 H

1000 H = 1 KH

1000 KH = 1 MH

Applications

An inductor with two 47mH windings, as may be found in a power supply.

Inductors are used extensively in analog circuits and signal processing. Inductors in conjunction with capacitors and other components form tuned circuits which can emphasize or filter out specific signal frequencies. Applications range from the use of large inductors in power supplies, which in conjunction with filter capacitors remove residual hums known as the Mains hum or other fluctuations from the direct current output, to the small inductance of the ferrite bead or torus installed around a cable to

Prevent radio frequency interference from being transmitted down the wire. Smaller inductor/capacitor combinations provide tuned circuits used in radio reception and broadcasting, for instance.

Two (or more) inductors which have coupled magnetic flux form a transformer, which is a fundamental component of every electric utility power grid. The efficiency of a transformer may decrease as the frequency increases due to eddy currents in the core material and skin effect on the windings. Size of the core can be decreased at higher frequencies and, for this reason, aircraft use 400 hertz alternating current rather than the usual 50 or 60 hertz, allowing a great saving in weight from the use of smaller transformers.

An inductor is used as the energy storage device in some switched-mode power supplies. The inductor is energized for a specific fraction of the regulator's switching frequency, and de-energized for the remainder of the cycle. This energy transfer ratio determines the input-voltage to output-voltage ratio. This X_L is used in complement with an active semiconductor device to maintain very accurate voltage control.

Inductors are also employed in electrical transmission systems, where they are used to depress voltages from lightning strikes and to limit switching currents and fault current. In this field, they are more commonly referred to as reactors.

Larger value inductors may be simulated by use of gyrator circuits.

Inductor construction

An inductor is usually constructed as a coil of conducting material, typically copper wire, wrapped around a core either of air or of ferromagnetic material. Core materials with a higher permeability than air increase the magnetic field and confine it closely to the inductor, thereby increasing the inductance. Low frequency inductors are constructed like transformers, with cores of electrical steel laminated to prevent eddy currents. 'Soft' ferrites are widely used for cores above audio frequencies, since they don't cause the large energy losses at high frequencies that ordinary iron alloys do. This is because of their narrow hysteresis curves, and their high resistivity prevents eddy currents. Inductors come in many shapes. Most are constructed as enamel coated wire wrapped around a ferrite bobbin with wire exposed on the outside, while some enclose the wire completely in ferrite and are called "shielded". Some inductors have an adjustable core, which enables changing of the inductance. Inductors used to block very high frequencies are sometimes made by stringing a ferrite cylinder or bead on a wire.

Small inductors can be etched directly onto a printed circuit board by laying out the trace in a spiral pattern. Some such planar inductors use a planar core.

Small value inductors can also be built on integrated circuits using the same processes that are used to make transistors. Aluminum interconnect is typically used, laid out in a spiral coil pattern. However, the small dimensions limit the inductance, and it is far more common to use a circuit called a "gyrator" which uses a capacitor and active components to behave similarly to an inductor.

Transformer

Output: low voltage AC

Transformers convert AC electricity from one voltage to another with little loss of power. Transformers work only with AC and this is one of the reasons why mains electricity is AC.

Step-up transformers increase voltage, step-down transformers reduce voltage. Most power supplies use a step-down transformer to reduce the dangerously high mains voltage (230V in UK) to a safer low voltage.

The input coil is called the **primary** and the output coil is called the **secondary**. There is no electrical connection between the two coils, instead they are linked by an alternating magnetic field created in the soft-iron core of the transformer. The two lines in the middle of the circuit symbol represent the core.

Transformers waste very little power so the power out is (almost) equal to the power in. Note that as voltage is stepped down current is stepped up.

The ratio of the number of turns on each coil, called the **turn's ratio**, determines the ratio of the voltages. A step-down transformer has a large number of turns on its primary (input) coil which is connected to the high voltage mains supply, and a small number of turns on its secondary (output) coil to give a low output voltage.

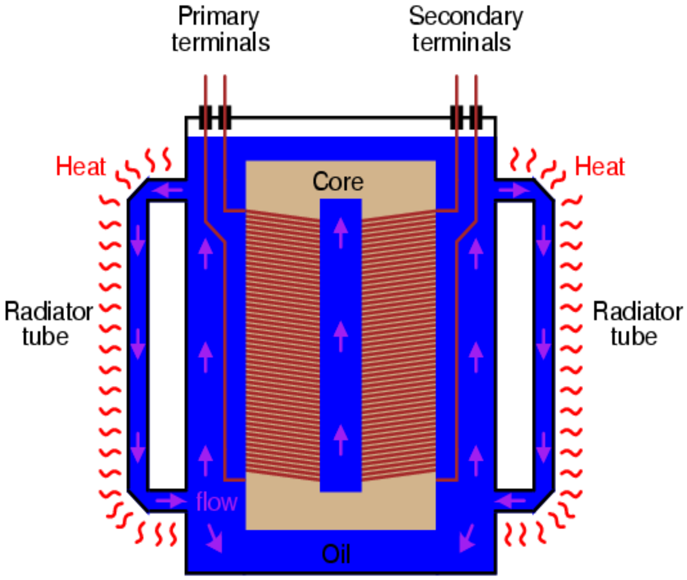
A variety of types of electrical transformer are made for different purposes. Despite their design differences, the various types employ the same basic principle as discovered in 1831 by Michael Faraday, and share several key functional parts.

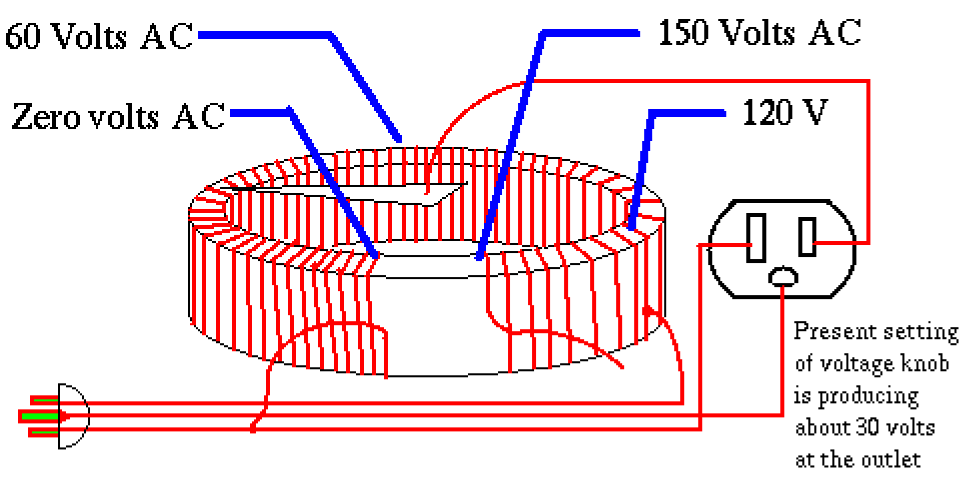
Power transformers



This is the most common type of transformer, widely used in appliances to convert mains voltage to low voltage to power electronics

- Widely available in power ratings ranging from mW to MW
- Insulated laminations minimize eddy current losses
- Small appliance and electronic transformers may use a split bobbin, giving a high level of insulation between the windings
- Rectangular core
- Core laminate stampings are usually in EI shape pairs. Other shape pairs are sometimes used.
- Mumetal shields can be fitted to reduce EMI (electromagnetic interference)
- A screen winding is occasionally used between the 2 power windings
- Small appliance and electronics transformers may have a thermal cut out built in
- Occasionally seen in low profile format for use in restricted spaces
- laminated core made with silicon steel with high permeability

Variac / Autotransformer



60 Volts AC
Zero volts AC
150 Volts AC
120 V
Present setting of voltage knob is producing about 30 volts at the outlet

An autotransformer has only a single winding, which is tapped at some point along the winding. AC or pulsed voltage is applied across a portion of the winding, and a higher (or lower) voltage is produced across another portion of the same winding. While theoretically separate parts of the winding can be used for input and output, in practice the higher voltage will be connected to the ends of the winding, and the lower voltage from one end to a tap. For example, a transformer with a tap at the center of the winding can be used with 230 volts across the entire winding, and 115 volts between one end and the tap. It can be connected to a 230-volt supply to drive 115-volt equipment, or reversed to drive 230-volt equipment from 115 volts. Since the current in the

Windings is lower, the transformer is smaller, lighter cheaper and more efficient. For voltage ratios not exceeding about 3:1, an autotransformer is cheaper, lighter, smaller and more efficient than an isolating (two-winding) transformer of the same rating.

In practice, transformer losses mean that autotransformers are not perfectly reversible; one designed for stepping down a voltage will deliver slightly less voltage than required if used to step up. The difference is usually slight enough to allow reversal where the actual voltage level is not critical. This is true of isolated winding transformers too.

By exposing part of the winding coils of an autotransformer, and making the secondary connection through a sliding carbon brush, an autotransformer with a near-continuously variable turns ratio can be obtained, allowing for wide voltage adjustment in very small increments.

Constant voltage transformer (Ferro-resonance)

By arranging particular magnetic properties of a transformer core, and installing a resonant tank circuit (a capacitor and an additional winding), a transformer can be arranged to automatically keep the secondary winding voltage constant regardless (within some limits) of any variance in the primary supply without additional circuitry or manual adjustment. CVA transformers run hotter than standard power transformers, for the regulating action is dependent on core saturation, which reduces efficiency somewhat. The output waveform features heavy distortion

Ferrite Core

Ferrite core power transformers are widely used in switched mode power supplies (SMPSUs). The powder core enables high frequency operation, and hence much smaller size to power ratio than laminated iron transformers.

Ferrite transformers are not usable as power transformers at mains frequency

Current transformers

Current transformers used in metering equipment for three-phase 400 ampere electricity supply

A current transformer (CT) is a measurement device designed to provide a current in its secondary coil proportional to the current flowing in its primary. Current transformers are commonly used in metering and protective relaying in the electrical power industry where they facilitate the safe measurement of large currents, often in the presence of high voltages. The current transformer safely isolates measurement and control circuitry from the high voltages typically present on the circuit being measured.

Current transformers are often constructed by passing a single primary turn (either an insulated cable or an uninsulated bus bar) through a well-insulated toroidal core wrapped with many turns of wire. The CT is typically described by its current ratio from primary to secondary. For example, a 4000:5 CT would provide an output current of 5 amperes when the primary was passing 4000 amperes. The secondary winding can be single ratio or have several tap points to provide a range of ratios. Care must be taken that the secondary winding is not disconnected from its load while current flows in the primary, as this will produce a dangerously high voltage across the open secondary and may permanently affect the accuracy of the transformer.

Specially constructed wideband CTs are also used, usually with an oscilloscope, to measure high frequency waveforms or pulsed currents within pulsed power systems. One type provides a voltage output that is proportional to the measured current; another, called a Rogowski coil, requires an external integrator in order to provide a proportional output.

Voltage transformers

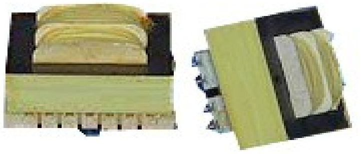
Voltage transformers (VTs) or potential transformers (PTs) are another type of instrument transformer, used for metering and protection in high-voltage circuits. They are designed to present negligible load to the supply being measured and to have a precise voltage ratio to accurately step down high voltages so that metering and protective relay equipment can be operated at a lower potential. Typically the secondary of a voltage transformer is rated for 69 or 120 Volts at rated primary voltage, to match the input ratings of protection relays.

The transformer winding high-voltage connection points are typically labelled as H1, H2 (sometimes H0 if it is internally grounded) and X1, X2, and sometimes an X3 tap may be present. Sometimes a second isolated winding (Y1, Y2, Y3) may also be available on the same voltage transformer. The high side (primary) may be connected phase to ground or phase to phase. The low side (secondary) is usually phase to ground.

The terminal identifications (H1, X1, Y1, etc.) are often referred to as polarity. This applies to current transformers as well. At any instant terminals with the same suffix numeral have the same polarity and phase. Correct identification of terminals and wiring is essential for proper operation of metering and protection relays.

While VTs were formerly used for all voltages greater than 240V primary, modern meters eliminate the need VTs for most secondary service voltages. VTs are typically used in circuits where the system voltage level is above 600 V. Modern meters eliminate the need of VT's since the voltage remains constant and it is measured in the incoming supply.

Pulse transformers



A **pulse transformer** is a transformer that is optimised for transmitting rectangular electrical pulses (that is, pulses with fast rise and fall times and a relatively constant amplitude). Small versions called *signal* types are used in digital logic and telecommunications circuits, often for matching logic drivers to transmission lines. Medium-sized *power* versions are used in power-control circuits such as camera flash controllers. Larger *power* versions are used in the electrical power distribution industry to interface low-voltage control circuitry to the high-voltage gates of power semiconductors. Special high voltage pulse transformers are also used to generate high power pulses for radar, particle accelerators, or other high energy pulsed power applications.

To minimise distortion of the pulse shape, a pulse transformer needs to have low values of leakage inductance and distributed capacitance, and a high open-circuit inductance. In power-type pulse transformers, a low coupling capacitance (between the primary and secondary) is important to protect the circuitry on the primary side from high-powered transients created by the load. For the same reason, high insulation resistance and high breakdown voltage are required. A good transient response is necessary to maintain the rectangular pulse shape at the secondary, because a pulse with slow edges would create switching losses in the power semiconductors.

The product of the peak pulse voltage and the duration of the pulse (or more accurately, the voltage-time integral) is often used to characterise pulse transformers. Generally speaking, the larger this product, the larger and more expensive the transformer.

Pulse transformers by definition have a duty cycle of less than 1, whatever energy stored in the coil during the pulse must be "dumped" out before the pulse is fired again.

Air-core transformers

These are used for high frequency work. The lack of a core means very low inductance. Such transformers may be nothing more than a few turns of wire soldered onto a printed circuit board.

Ferrite-core transformers

Widely used in intermediate frequency (IF) stages in super heterodyne radio receivers. These are mostly tuned transformers, containing a threaded ferrite slug that is screwed in or out to adjust IF tuning. The transformers are usually canned for stability and to reduce interference

Audio transformers

Transformers in a tube amplifier. Output transformers are on the left. The power supply toroidal transformer is on right.

Audio transformers are usually the factor which limits sound quality when used; electronic circuits with wide frequency response and low distortion are relatively simple to design.

Transformers are also used in DI boxes to convert high-impedance instrument signals (e.g. bass guitar) to low impedance signals to enable them to be connected to a microphone input on the mixing console.

A particularly critical component is the output transformer of an audio power amplifier. Valve circuits for quality reproduction have long been produced with no other (inter-stage) audio transformers, but an output transformer is needed to couple the relatively high impedance (up to a few hundred ohms depending upon configuration) of the output valve(s) to the low impedance of a loudspeaker. (The valves can deliver a low current at a high voltage; the speakers require high current at low voltage.) Most solid-state power amplifiers need no output transformer at all.

For good low-frequency response a relatively large iron core is required; high power handling increases the required core size. Good high-frequency response requires carefully designed and implemented windings without excessive leakage inductance or stray capacitance. All this makes for an expensive component.

Early transistor audio power amplifiers often had output transformers, but they were eliminated as designers discovered how to design amplifiers without them.

Capacitors

Function

Capacitors store electric charge. They are used with resistors in timing circuits because it takes time for a capacitor to fill with charge. They are used to smooth varying DC supplies by acting as a reservoir of charge. They are also used in filter circuits because capacitors easily pass AC (changing) signals but they block DC (constant) signals.

Capacitance

This is a measure of a capacitor's ability to store charge. A large capacitance means that more charge can be stored. Capacitance is measured in farads, symbol F. However 1F is very large, so prefixes are used to show the smaller values.

Three prefixes (multipliers) are used, µ (micro), n (nano) and p (pico):

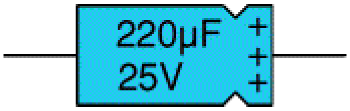
- µ means 10^{-6} (millionth), so 1000000µF = 1F
- n means 10^{-9} (thousand-millionth), so 1000nF = 1µF
- p means 10^{-12} (million-millionth), so 1000pF = 1nF

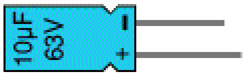
Capacitor values can be very difficult to find because there are many types of capacitor with different labeling systems!

There are many types of capacitor but they can be split into two groups, **polarised** and **unpolarised**. Each group has its own circuit symbol.

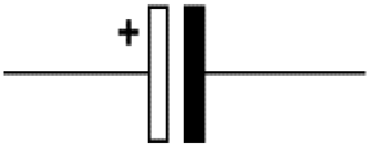
Polarised capacitors (large values, 1µF +)

Examples:

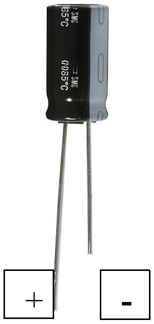




Circuit symbol:



Electrolytic Capacitors

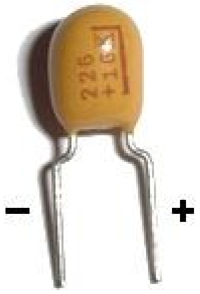


Electrolytic capacitors are polarised and **they must be connected the correct way round**, at least one of their leads will be marked + or -. They are not damaged by heat when soldering.

There are two designs of electrolytic capacitors; **axial** where the leads are attached to each end (220µF in picture) and **radial** where both leads are at the same end (10µF in picture). Radial capacitors tend to be a little smaller and they stand upright on the circuit board.

It is easy to find the value of electrolytic capacitors because they are clearly printed with their capacitance and voltage rating. The voltage rating can be quite low (6V for example) and it should always be checked when selecting an electrolytic capacitor. If the project parts list does not specify a voltage, choose a capacitor with a rating which is greater than the project's power supply voltage. 25V is a sensible minimum most battery circuits.

Tantalum Bead Capacitors



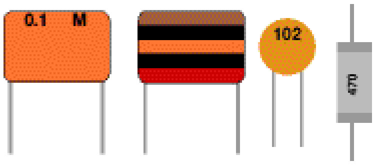
Tantalum bead capacitors are polarised and have low voltage ratings like electrolytic capacitors. They are expensive but very small, so they are used where a large capacitance is needed in a small size.

Modern tantalum bead capacitors are printed with their capacitance, voltage and polarity in full. However older ones use a colour-code system which has two stripes (for the two digits) and a spot of colour for the number of zeros to give the value in µF. The standard colour code is used, but for the spot, **grey** is used to mean × 0.01 and **white** means × 0.1 so that values of less than 10µF can be shown. A third colour stripe near the leads shows the voltage (yellow 6.3V, black 10V, green 16V, blue 20V, grey 25V, white 30V, pink 35V). The positive (+) lead is to the right when the spot is facing you: '**when the spot is in sight, the positive is to the right**'.

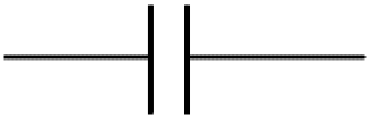
For	example:	**blue,**	**grey,**	**black**	**spot**	means	68µF
For	example:	**blue,**	**grey,**	**white**	**spot**	means	6.8µF
For	example:	**blue,**	**grey,**	**grey**	**spot**	means	0.68µF

Unpolarised capacitors (small values, up to 1µF)

Examples:

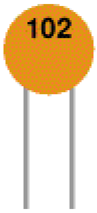


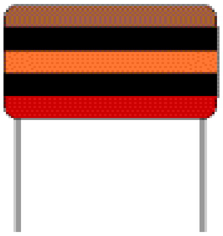
Circuit symbol:

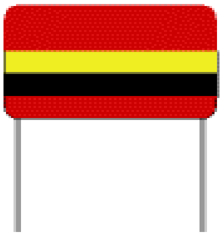


Small value capacitors are unpolarised and may be connected either way round. They are not damaged by heat when soldering, except for one unusual type (polystyrene). They have high voltage ratings of at least 50V, usually 250V or so. It can be difficult to find the values of these small capacitors because there are many types of them and several different labelling systems!

Many small value capacitors have their value printed but without a multiplier, so you need to use experience to work out what the multiplier should be!







For example **0.1** means 0.1µF = 100nF.

Sometimes the multiplier is used in place of the decimal point:
For example: **4n7** means 4.7nF.

Capacitor Number Code

A number code is often used on small capacitors where printing is difficult:

- the 1st number is the 1st digit,
- the 2nd number is the 2nd digit,
- the 3rd number is the number of zeros to give the capacitance in pF.
- Ignore any letters - they just indicate tolerance and voltage rating.

For example: **102** means 1000pF = 1nF *(not 102pF!)*

For example: **472J** means 4700pF = 4.7nF (J means 5% tolerance).

Capacitor Colour Code

Colour Code	
Colour	Number
Black	0
Brown	1
Red	2
Orange	3
Yellow	4
Green	5
Blue	6
Violet	7
Grey	8
White	9

A colour code was used on polyester capacitors for many years. It is now obsolete, but of course there are many still around. The colours should be read like the resistor code, the top three colour bands giving the value in pF. Ignore the 4th band (tolerance) and 5th band (voltage rating).

For example:

Brown, black, orange means 10000pF = 10nF = 0.01µF.

Note that there are no gaps between the colour bands, so 2 identical bands actually appear as a wide band.

For example:

Wide red, yellow means 220nF = 0.22µF.

This type is rarely used now. Their value (in pF) is normally printed without units. Polystyrene capacitors can be damaged by heat when soldering (it melts the polystyrene!) so you should use a heat sink (such as a crocodile clip). Clip the heat sink to the lead between the capacitor and the joint.

Real capacitor values (the E3 and E6 series)

You may have noticed that capacitors are not available with every possible value, for example 22µF and 47µF are readily available, but 25µF and 50µF are not!

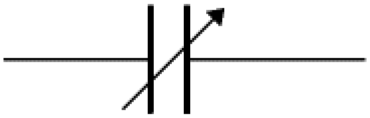
Why is this? Imagine that you decided to make capacitors every 10µF giving 10, 20, 30, 40, 50 and so on. That seems fine, but what happens when you reach 1000? It would be pointless to make 1000, 1010, 1020, 1030 and so on because for these values 10 is a very small difference, too small to be noticeable in most circuits and capacitors cannot be made with that accuracy.

To produce a sensible range of capacitor values you need to increase the size of the 'step' as the value increases. The standard capacitor values are based on this idea and they form a series which follows the same pattern for every multiple of ten.

The E3 series (3 values for each multiple of ten)
10, 22, 47, ... then it continues 100, 220, 470, 1000, 2200, 4700, 10000 etc.
Notice how the step size increases as the value increases (values roughly double each time).

The E6 series (6 values for each multiple of ten)
10, 15, 22, 33, 47, 68, ... then it continues 100, 150, 220, 330, 470, 680, 1000 etc.
Notice how this is the E3 series with an extra value in the gaps.

The E3 series is the one most frequently used for capacitors because many types cannot be made with very accurate values.



Variable Capacitor Symbol

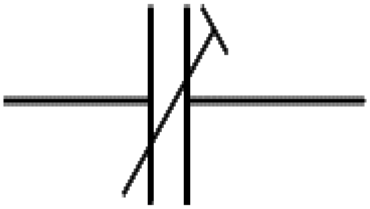
Variable capacitors

Variable capacitors are mostly used in radio tuning circuits and they are sometimes called 'tuning capacitors'. They have very small capacitance values, typically between 100pF and 500pF (100pF = 0.0001µF). The type illustrated usually has trimmers built in (for making small adjustments - see below) as well as the main variable capacitor.

Variable Capacitor

Many variable capacitors have very short spindles which are not suitable for the standard knobs used for variable resistors and rotary switches. It would be wise to check that a suitable knob is available before ordering a variable capacitor.

Variable capacitors are **not** normally used in timing circuits because their capacitance is too small to be practical and the range of values available is very limited. Instead timing circuits use a fixed capacitor and a variable resistor if it is necessary to vary the time period.



Trimmer Capacitor Symbol

Trimmer capacitors

Trimmer capacitors (trimmers) are miniature variable capacitors. They are designed to be mounted directly onto the circuit board and adjusted only when the circuit is built.

Trimmer Capacitor

A small screwdriver or similar tool is required to adjust trimmers. The process of adjusting them requires patience because the presence of your hand and the tool will slightly change the capacitance of the circuit in the region of the trimmer!

Trimmer capacitors are only available with very small capacitances, normally less than 100pF. It is impossible to reduce their capacitance to zero, so they are usually specified by their minimum and maximum values, for example 2-10pF.

Trimmers are the capacitor equivalent of presets which are miniature variable resistors.

Standard Switches

Type of Switch	Circuit Symbol	Example
ON-OFF **Single Pole, Single Throw = SPST** A simple on-off switch. This type can be used to switch the power supply to a circuit. When used with mains electricity this type of switch *must* be in the live wire, but it is better to use a DPST switch to isolate both live and neutral.		 SPST toggle switch
(ON)-OFF **Push-to-make = SPST Momentary** A push-to-make switch returns to its normally open (off) position when you release the button, this is shown by the brackets around ON. This is the standard doorbell switch.		 Push-to-make switch
ON-(OFF) **Push-to-break = SPST Momentary** A push-to-break switch returns to its normally closed (on) position when you release the button.		 Push-to-break switch

ON-ON **Single Pole, Double Throw = SPDT** This switch can be on in both positions, switching on a separate device in each case. It is often called a **changeover switch.** For example, a SPDT switch can be used to switch on a red lamp in one position and a green lamp in the other position. A SPDT toggle switch may be used as a simple on-off switch by connecting to COM and one of the A or B terminals shown in the diagram. A and B are interchangeable so switches are usually not labelled. **ON-OFF-ON** **SPDT Centre Off** A special version of the standard SPDT switch. It has a third switching position in the centre which is off. Momentary (ON)-OFF-(ON) versions are also available where the switch returns to the central off position when released.	 	 SPDT toggle switch SPDT slide switch (PCB mounting) SPDT rocker switch
Dual ON-OFF **Double Pole, Single Throw = DPST** A pair of on-off switches which operate together (shown by the dotted line in the circuit symbol). A DPST switch is often used to switch mains electricity because it can isolate both the live and neutral connections.		 DPST rocker switch

Special Switches

Type of Switch	Example

Push-Push Switch (e.g. SPST = ON-OFF)

This looks like a momentary action push switch but it is a standard on-off switch: push once to switch on, push again to switch off. This is called a **latching action**.

Micro switch (usually SPDT = ON-ON)

Micro switches are designed to switch fully open or closed in response to small movements. They are available with levers and rollers attached.

Key switch

A key operated switch. The example shown is SPST.

Tilt Switch (SPST)

Tilt switches contain a conductive liquid and when tilted this bridges the contacts inside, closing the switch. They can be used as a sensor to detect the position of an object. Some tilt switches contain mercury which is poisonous.

Reed Switch (usually SPST)

The contacts of a reed switch are closed by bringing a small magnet near the switch. They are used in security circuits, for example to check that doors are closed. Standard reed switches are SPST (simple on-off) but SPDT (changeover) versions are also available.

DIP Switch (DIP = Dual In-line Parallel)

This is a set of miniature SPST on-off switches, the example shown has 8 switches. The package is the same size as a standard DIL (Dual In-Line) integrated circuit.

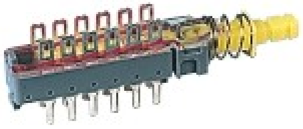
This type of switch is used to set up circuits, e.g. setting the code of a remote control.

Multi-pole Switch

The picture shows a 6-pole double throw switch, also known as a 6-pole changeover switch. It can be set to have momentary or latching action. Latching action means it behaves as a push-push switch, push once for the first position, push again for the second position etc.



Multi-way Switch

Multi-way switches have 3 or more conducting positions. They may have several poles (contact sets). A popular type has a rotary action and it is available with a range of contact arrangements from 1-pole 12-way to 4-pole 3 way.

The number of ways (switch positions) may be reduced by adjusting a stop under the fixing nut. For example if you need a 2-pole 5-way switch you can buy the 2-pole 6-way version and adjust the stop.

Contrast this multi-way switch (many switch positions) with the multi-pole switch (many contact sets) described above.

Relays

A relay is an electrically operated switch. Current flowing through the coil of the relay creates a magnetic field which attracts a lever and changes the switch contacts. The coil current can be on or off so relays have two switch positions and they are double throw (changeover) switches.

Relays allow one circuit to switch a second circuit which can be completely separate from the first. For example a low voltage battery circuit can use a relay to switch a 230V AC mains circuit. There is no electrical connection inside the relay between the two circuits, the link is magnetic and mechanical.

The coil of a relay passes a relatively large current, typically 30mA for a 12V relay, but it can be as much as 100mA for relays designed to operate from lower voltages. Most ICs (chips) cannot provide this current and a transistor is usually used to amplify the small IC current to the larger value required for the relay coil. The maximum output current for the popular 555 timer IC is 200mA so these devices can supply relay coils directly without amplification.

Relays are usuallly SPDT or DPDT but they can have many more sets of switch contacts, for example relays with 4 sets of changeover contacts are readily available. For further information about switch contacts and the terms used to describe them please see the page on switches.

Most relays are designed for PCB mounting but you can solder wires directly to the pins providing you take care to avoid melting the plastic case of the relay.

The supplier's catalogue should show you the relay's connections. The coil will be obvious and it may be connected either way round. Relay coils produce brief high voltage 'spikes' when they are switched off and this can destroy transistors and ICs in the circuit. To prevent damage you must connect a protection diode across the relay coil.

The animated picture shows a working relay with its coil and switch contacts. You can see a lever on the left being attracted by magnetism when the coil is switched on. This lever moves the switch contacts. There is one set of contacts (SPDT) in the foreground and another behind them, making the relay DPDT.

The relay's switch connections are usually labelled COM, NC and NO:

COM = Common, always connect to this, it is the moving part of the switch.

NC = Normally Closed, COM is connected to this when the relay coil is off.

NO = Normally Open, COM is connected to this when the relay coil is on.

Connect to COM and NO if you want the switched circuit to be on when the relay coil is on.

Connect to COM and NC if you want the switched circuit to be on when the relay coil is off.

Choosing a relay

You need to consider several features when choosing a relay:

Physical size and pin arrangement

If you are choosing a relay for an existing PCB you will need to ensure that its dimensions and pin arrangement are suitable. You should find this information in the supplier's catalogue.

Coil voltage

The relay's coil voltage rating and resistance must suit the circuit powering the relay coil. Many relays have a coil rated for a 12V supply but 5V and 24V relays are also readily available. Some relays operate perfectly well with a supply voltage which is a little lower than their rated value.

Coil resistance

The circuit must be able to supply the current required by the relay coil. You can use Ohm's law to calculate the current: Relay coil current = supply voltage

Coil resistance

For example: A 12V supply relay with a coil resistance of 400 passes a current of 30mA. This is OK for a 555 timer IC (maximum output current 200mA), but it is too much for most ICs and they will require a transistor to amplify the current.

Switch ratings (voltage and current)

The relay's switch contacts must be suitable for the circuit they are to control. You will need to check the voltage and current ratings. Note that the voltage rating is usually higher for AC, for example: "5A at 24V DC or 125V AC".

Switch contact arrangement (SPDT, DPDT etc)

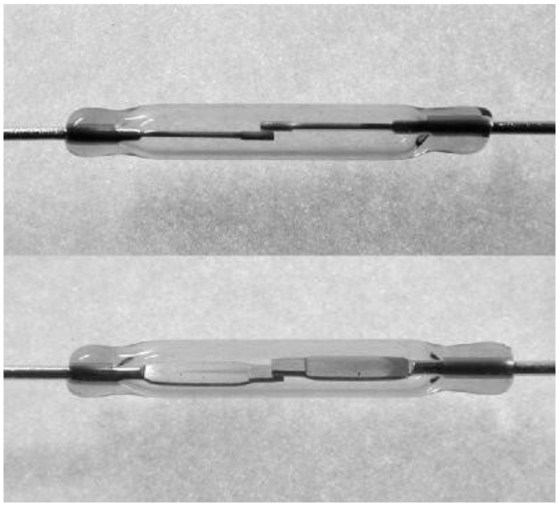
Most relays are SPDT or DPDT which are often described as "single pole changeover" (SPCO) or "double pole changeover" (DPCO). For further information please see the page on switches.

Protection diodes for relays

Transistors and ICs must be protected from the brief high voltage produced when a relay coil is switched off. The diagram shows how a signal diode (eg 1N4148) is connected 'backwards' across the relay coil to provide this protection.

Current flowing through a relay coil creates a magnetic field which collapses suddenly when the current is switched off. The sudden collapse of the magnetic field induces a brief high voltage across the relay coil which is very likely to damage transistors and ICs. The protection diode allows the induced voltage to drive a brief current through the coil (and diode) so the magnetic field dies away quickly rather than instantly. This prevents the induced voltage becoming high enough to cause damage to transistors and ICs.

Reed relays



_

Reed relays consist of a coil surrounding a reed switch. Reed switches are normally operated with a magnet, but in a reed relay current flows through the coil to create a magnetic field and close the reed switch.

Reed relays generally have higher coil resistances than standard relays (1000 for example) and a wide range of supply voltages (9-20V for example). They are capable of switching much more rapidly than standard relays, up to several hundred times per second; but they can only switch low currents (500mA maximum for example).

The reed relay shown in the photograph will plug into a standard 14-pin DIL socket ('IC holder').

For further information about reed switches please see the page on switche

Diode

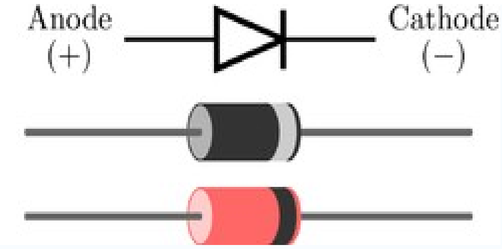

Figure 1: Closeup of a diode, showing the square shaped semiconductor crystal

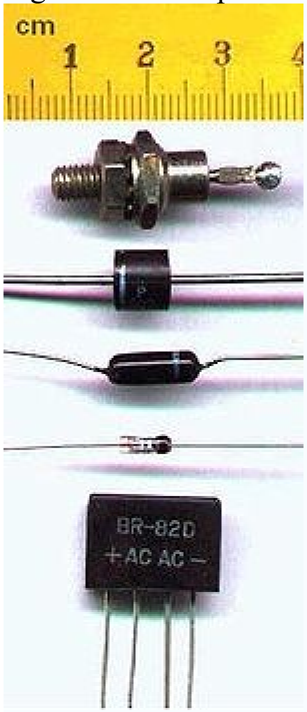

In electronics, a **diode** is a two-terminal device (thermionic diodes may also have one or two ancillary terminals for a heater).

Diodes have two active electrodes between which the signal of interest may flow, and most are used for their unidirectional electric current property. The varicap diode is used as an electrically adjustable capacitor.

The directionality of current flow most diodes exhibit is sometimes generically called the *rectifying* property. The most common function of a diode is to allow an electric current to pass in one direction (called the *forward biased* condition) and to block the current in the opposite direction (the reverse biased condition). Thus, the diode can be thought of as an electronic version of a check valve.

Real diodes do not display such a perfect on-off directionality but have a more complex non-linear electrical characteristic, which depends on the particular type of diode technology. Diodes also have many other functions in which they are not designed to operate in this on-off manner.

Early diodes included “cat’s whisker” crystals and vacuum tube devices (also called **thermionic valves**). Today the most common diodes are made from semiconductor materials such as silicon or germanium

Semiconductor diodes

Most modern diodes are based on semiconductor p-n junctions. In a p-n diode, conventional current can flow from the p-type side (the anode) to the n-type side (the cathode), but cannot flow in the opposite direction. Another type of semiconductor diode, the Schottky diode, is formed from the contact between a metal and a semiconductor rather than by a p-n junction

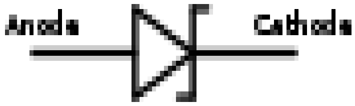
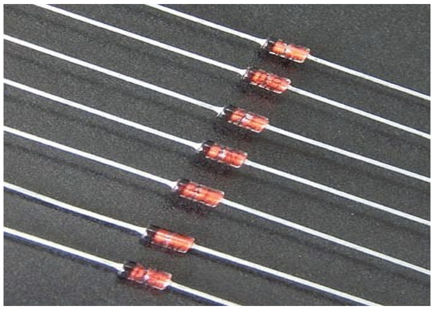
There are several types of junction diodes, which either emphasize a different physical aspect of a diode often by geometric scaling, doping level, choosing the right electrodes, are just an application of a diode in a special circuit, or are really different devices like the Gunn and laser diode and the MOSFET:

Normal (p-n) diodes, which operate as described above, are usually made of doped silicon or, more rarely, germanium. Before the development of modern silicon power rectifier diodes, cuprous oxide and later selenium was used; its low efficiency gave it a much higher forward voltage drop (typically 1.4–1.7 V per “cell”, with multiple cells stacked to increase the peak inverse voltage rating in high voltage rectifiers), and required a large heat sink (often an extension of the diode’s metal substrate), much larger than a silicon diode of the same current ratings would require. The vast majority of all diodes are the p-n diodes found in CMOS integrated circuits, which include two diodes per pin and many other internal diodes.

Zener diode





Zener diode schematic symbol

Current-voltage characteristic of a Zener diode with a breakdown voltage of 17 volt. Notice the change of voltage scale between the forward biased (positive) direction and the reverse biased (negative) direction.

A **Zener diode** is a type of diode that permits current in the forward direction like a normal diode, but also in the reverse direction if the voltage is larger than the breakdown voltage known as "Zener knee voltage" or "Zener voltage". The device was named after Clarence Zener, who discovered this electrical property.

A conventional solid-state diode will not allow significant current if it is reverse-biased below its reverse breakdown voltage. When the reverse bias breakdown voltage is exceeded, a conventional diode is subject to high current due to avalanche breakdown. Unless this current is limited by external circuitry, the diode will be permanently damaged. In case of large forward bias (current in the direction of the arrow), the diode exhibits a voltage drop due to its junction built-in voltage and internal resistance. The amount of the voltage drop depends on the semiconductor material and the doping concentrations.

A **Zener diode** exhibits almost the same properties, except the device is specially designed so as to have a greatly reduced breakdown voltage, the so-called **Zener voltage**. A Zener diode contains a heavily doped p-n junction allowing electrons to tunnel from the valence band of the p-type material to the conduction band of the n-type material. In the atomic scale, this tunneling corresponds to the transport of valence band electrons into the empty conduction band states; as a result of the reduced barrier between these bands and high electric fields that are induced due to the relatively high levels of dopings on both sides. A reverse-biased Zener diode will exhibit a controlled breakdown and allow the current to keep the voltage across the Zener diode at the Zener voltage. For example, a diode with a Zener breakdown voltage of 3.2 V will exhibit a voltage drop of 3.2 V if reverse bias voltage applied across it is more than its Zener voltage. However, the current is not unlimited, so the Zener diode is typically used to generate a reference voltage for an amplifier stage, or as a voltage stabilizer for low-current applications.

The breakdown voltage can be controlled quite accurately in the doping process. While tolerances within 0.05% are available, the most widely used tolerances are 5% and 10%.

Another mechanism that produces a similar effect is the avalanche effect as in the avalanche diode. The two types of diode are in fact constructed the same way and both effects are present in diodes of this type. In silicon diodes up to about 5.6 volts, the Zener effect is the predominant effect and shows a marked negative temperature coefficient. Above 5.6 volts, the avalanche effect becomes predominant and exhibits a positive temperature coefficient.

In a 5.6 V diode, the two effects occur together and their temperature coefficients neatly cancel each other out, thus the 5.6 V diode is the component of choice in temperature-critical applications.

Modern manufacturing techniques have produced devices with voltages lower than 5.6 V with negligible temperature coefficients, but as higher voltage devices are encountered, the temperature coefficient rises dramatically. A 75 V diode has 10 times the coefficient of a 12 V diode.

All such diodes, regardless of breakdown voltage, are usually marketed under the umbrella term of "Zener diode".

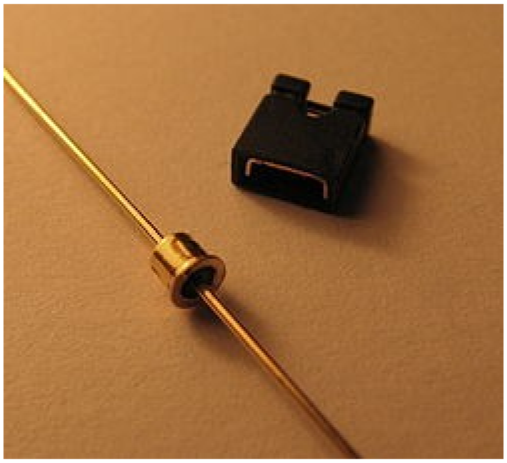
Uses

Zener diode shown with typical packages. *Reverse* current − i_Z is shown.

Zener diodes are widely used to regulate the voltage across a circuit. When connected in parallel with a variable voltage source so that it is reverse biased, a Zener diode conducts when the voltage reaches the diode's reverse breakdown voltage. From that point it keeps the voltage at that value.

Tunnel diode

Tunnel diode schematic symbol



1N3716 tunnel diode (with jumper for scale)

A **tunnel diode** or **Esaki diode** is a type of semiconductor diode which is capable of very fast operation, well into the microwave frequency region, by using quantum mechanical effects.

It was invented in August 1957 by Leo Esaki when he was with Tokyo Tsushin Kogyo (now known as Sony), who in 1973 received the Nobel Prize in Physics for discovering the electron tunneling effect used in these diodes.

These diodes have a heavily doped p-n junction only some 10 nm (100 Å) wide. The heavy doping results in a broken bandgap, where conduction band electron states on the n-side are more or less aligned with valence band hole states on the p-side.

Tunnel diodes were manufactured by SONY for the first time in 1957 [1] followed by General Electric and other companies from about 1960, and are still made in low volume today. [2] Tunnel diodes are usually made from germanium, but can also be made in gallium arsenide and silicon materials. They can be used as oscillators, amplifiers, frequency converters and detectors. [3]

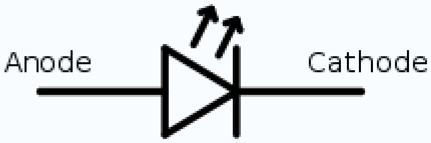
.

Blue, green, and red LEDs; these can be combined to produce most perceptible colors, including white. Infrared and ultraviolet (UVA) LEDs are also available.



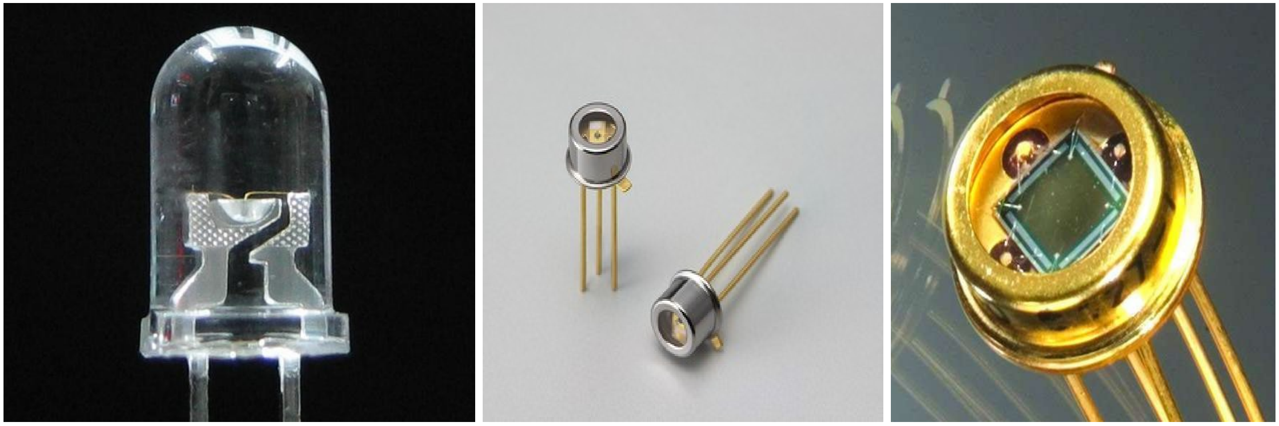
LED schematic symbol

.

A **light-emitting-diode** (**LED**) is a semiconductor diode that emits light when an electric current is applied in the forward direction of the device, as in the simple LED circuit. The effect is a form of electroluminescence where incoherent and narrow-spectrum light is emitted from the p-n junction in a solid state material.

LEDs are widely used as indicator lights on electronic devices and increasingly in higher power applications such as flashlights and area lighting. An LED is usually a small area (less than 1 mm^2) light source, often with optics added directly on top of the chip to shape its radiation pattern and assist in reflection.[2][3] The color of the emitted light depends on the composition and condition of the semi conducting material used, and can be infrared, visible, or ultraviolet. Besides lighting, interesting applications include using UV-LEDs for sterilization of water and disinfection of devices,[4] and as a grow light to enhance photosynthesis in plants.[5]

Photodiode



A photodiode

A **photodiode** is a type of photodetector capable of converting light into either current or voltage, depending upon the mode of operation.[1]

Photodiodes are similar to regular semiconductor diodes except that they may be either exposed (to detect vacuum UV or X-rays) or packaged with a window or optical fibre connection to allow light to reach the sensitive part of the device. Many diodes designed for use specifically as a photodiode will also use a PIN junction rather than the typical PN junction.

In electronics, a **varicap diode**, **varactor diode**, **variable capacitance diode** or **tuning diode** is a type of diode which has a variable capacitance that is a function of the voltage impressed on its terminals._

Applications

Varactors are principally used as a voltage-controlled capacitor, rather than as rectifiers. They are commonly used in parametric amplifiers, parametric oscillators and voltage-controlled oscillators as part of phase-locked loops and frequency synthesizers.

Some electronic circuits require a power supply with positive and negative outputs as well as zero volts (0V). This is called a 'dual supply' because it is like two ordinary supplies connected together as shown in the diagram.

Dual supplies have three outputs, for example a ±9V supply has +9V, 0V and -9V outputs.

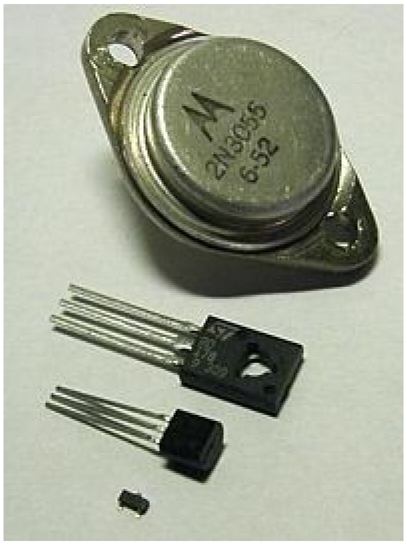
Transistors

Function

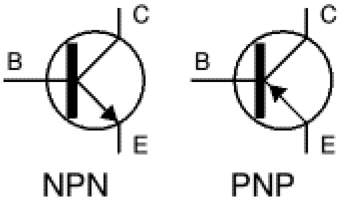
Transistors **amplify current**, for example they can be used to amplify the small output current from a logic IC so that it can operate a lamp, relay or other high current device. In many circuits a resistor is used to convert the changing current to a changing voltage, so the transistor is being used to **amplify voltage**.

A transistor may be used as a **switch** (either fully on with maximum current, or fully off with no current) and as an **amplifier** (always partly on).

The amount of current amplification is called the **current gain**, symbol h_{FE}. For further information please see the Transistor Circuits page.



Types of transistor



Transistor circuit symbols

There are two types of standard transistors, **NPN** and **PNP**, with different circuit symbols. The letters refer to the layers of semiconductor material used to make the transistor. Most transistors used today are NPN because this is the easiest type to make from silicon. If you are new to electronics it is best to start by learning how to use NPN transistors.

The leads are labelled **base** (B), **collector** (C) and **emitter** (E). These terms refer to the internal operation of a transistor but they are not much help in understanding how a transistor is used, so just treat them as labels!

NPN

The symbol of an NPN Bipolar Junction Transistor.

NPN is one of the two types of bipolar transistors, in which the letters "N" and "P" refer to the majority charge carriers inside the different regions of the transistor. Most bipolar transistors used today are NPN, because electron mobility is higher than hole mobility in semiconductors, allowing greater currents and faster operation.

NPN transistors consist of a layer of P-doped semiconductor (the "base") between two N-doped layers. A small current entering the base in common-emitter mode is amplified in the collector output. In other terms, an NPN transistor is "on" when its base is pulled **high** relative to the emitter.

The arrow in the NPN transistor symbol is on the emitter leg and points in the direction of the conventional current flow when the device is in forward active mode.

One mnemonic device for identifying the symbol for the NPN transistor is "**n**ot **p**ointing i**n**"[5] or "**n**ever **p**oints i**n**".

PNP

The other type of BJT is the PNP with the letters "P" and "N" referring to the majority charge carriers inside the different regions of the transistor.

The symbol of a PNP Bipolar Junction Transistor.

PNP transistors consist of a layer of N-doped semiconductor between two layers of P-doped material. A small current leaving the base in common-emitter mode is amplified in the collector output. In other terms, a PNP transistor is "on" when its base is pulled **low** relative to the emitter.

The arrow in the PNP transistor symbol is on the emitter leg and points in the direction of the conventional current flow when the device is in forward active mode.

One mnemonic device for identifying the symbol for the PNP transistor is "**p**oints i**n** **p**roudly"[5] or "**p**oints i**n** **p**ermanently".

A Darlington pair is two transistors connected together to give a very high current gain.

In addition to standard (bipolar junction) transistors, there are **field-effect transistors** which are usually referred to as **FET**s. They have different circuit symbols and properties and they are not (yet) covered by this page.

Connecting

Transistors have three leads which must be connected the correct way round. Please take care with this because a wrongly connected transistor may be damaged instantly when you switch on.

If you are lucky the orientation of the transistor will be clear from the PCB or stripboard layout diagram, otherwise you will need to refer to a supplier's catalogue to identify the leads.

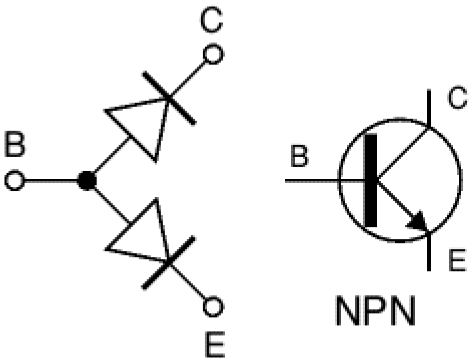
Testing a transistor

Transistors can be damaged by heat when soldering or by misuse in a circuit. If you suspect that a transistor may be damaged there are two easy ways to test it:

1. Testing with a multimeter

Use a multimeter or a simple tester (battery, resistor and LED) to check each pair of leads for conduction. Set a digital multimeter to diode test and an analogue multimeter to a low resistance range.



Testing an NPN transistor

Test each pair of leads both ways (six tests in total):

- The **base-emitter (BE)** junction should behave like a diode and conduct one way only.
- The **base-collector (BC)** junction should behave like a diode and conduct one way only.
- The **collector-emitter (CE)** should not conduct either way.

The diagram shows how the junctions behave in an NPN transistor. The diodes are reversed in a PNP transistor but the same test procedure can be used.

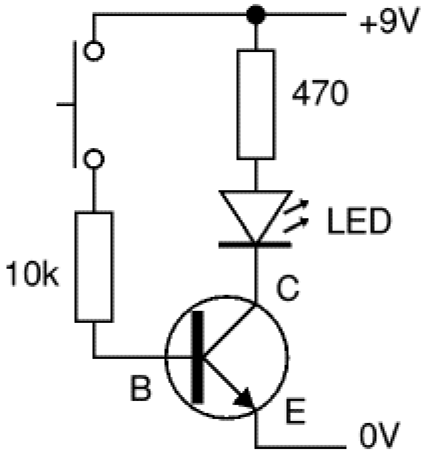
Testing in a simple switching circuit

Connect the transistor into the circuit shown on the right which uses the transistor as a switch. The supply voltage is not critical, anything between 5 and 12V is suitable. This circuit can be quickly built on breadboard for example. Take care to include the 10kΩ resistor in the base connection or you will destroy the transistor as you test it!

If the transistor is OK the LED should light when the switch is pressed and not light when the switch is released.

To test a PNP transistor use the same circuit but reverse the LED and the supply voltage.

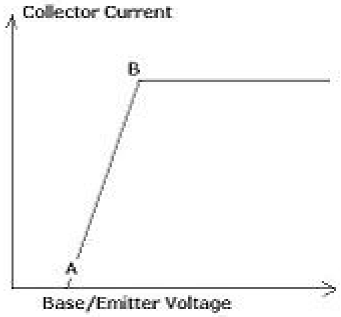
Some multimeters have a 'transistor test' function which provides a known base current and measures the collector current so as to display the transistor's DC current gain h_{FE}.



How a transistor works

Amplifier circuit, standard common-emitter configuration.

Simple circuit using a transistor.



Operation graph of a transistor.

The essential usefulness of a transistor comes from its ability to use a small signal applied between one pair of its terminals to control a much larger signal at another pair of terminals. This property is called "gain". A transistor can control its output in proportion to the input signal; this is called an "amplifier".

Or, the transistor can be used to turn current on or off in a circuit like an electrically controlled "switch", where the amount of current is determined by other circuit elements.

The two types of transistors have slight differences in how they are used in a circuit. A bipolar transistor has terminals labelled base, collector and emitter. A small current at base terminal can control or switch a much larger current between collector and emitter terminals. For a field-effect transistor, the terminals are labelled gate, source, and drain, and a voltage at the gate can control a current between source and drain.

The image to the right represents a typical bipolar transistor in a circuit. Charge will flow between emitter and collector terminals depending on the current in the base. Since internally the base and emitter connections behave like a semiconductor diode, a voltage drop develops between base and emitter while the base current exists. The size of this voltage depends on the material the transistor is made from, and is referred to as V_{be}.

Transistor as a switch

Transistors are commonly used as electronic switches, for both high power applications including switched-mode power supplies and low power applications such as logic gates.

It can be seen from the graph that once the base voltage reaches a certain level, shown at B, no more current will exist and the output will be held at a fixed voltage. The transistor is then said to be saturated. Hence, values of input voltage can be chosen such that the output is either completely off,[7] or completely on. The transistor is acting as a switch, and this type of operation is common in digital circuits where only "on" and "off" values are relevant.

Transistor as an amplifier

The above common emitter amplifier is designed so that a small change in voltage in (V_{in}) changes the small current through the base of the transistor and the transistor's current amplification combined with the properties of the circuit mean that small swings in V_{in} produce large changes in V_{out}.

It is important that the operating parameters of the transistor are chosen and the circuit designed such that as far as possible the transistor operates within a linear portion of the graph, such as that shown between A and B, otherwise the output signal will suffer distortion.

Various configurations of single transistor amplifier are possible, with some providing current gain, some voltage gain, and some both.

From mobile phones to televisions, vast numbers of products include amplifiers for sound reproduction, radio transmission, and signal processing. The first discrete transistor audio amplifiers barely supplied a few hundred milliwatts, but power and audio fidelity gradually increased as better transistors became available and amplifier architecture evolved.

Modern transistor audio amplifiers of up to a few hundred watts are common and relatively inexpensive.

Some musical instrument amplifier manufacturers mix transistors and vacuum tubes in the same circuit, as some believe tubes have a distinctive sound.

High-power N-channel field-effect transistor

The **field-effect transistor** (FET) is a type of transistor that relies on an electric field to control the shape and hence the conductivity of a channel of one type of charge carrier in a semiconductor material. FETs are sometimes called *unipolar transistors* to contrast their single-carrier-type operation with the dual-carrier-type operation of bipolar (junction) transistors (BJT). The *concept* of the FET predates the BJT, though it was not physically implemented until *after* BJTs due to the limitations of semiconductor materials and relative ease of manufacturing BJTs compared to FETs at the time.

Terminals

All FETs have a *gate*, *drain*, and *source* terminal that are roughly similar to the *base*, *collector*, and *emitter* of BJTs. Aside from the JFET, all FETs also have a fourth terminal called the *body*, *base*, *bulk*, or *substrate.* This fourth terminal serves the technical purpose of biasing the transistor into operation; it is rare to make non-trivial use of the body terminal in circuit designs, but its presence is important when setting up the physical layout of an integrated circuit.

Cross Section of an n-type MOSFET

The names of the terminals refer to their functions. The gate terminal may be thought of as controlling the opening and closing of a physical gate. This gate permits electrons to flow through or blocks their passage by creating or eliminating a channel between the source and drain. Electrons flow from the source terminal towards the drain terminal if influenced by an applied voltage. The body simply refers to the bulk of the semiconductor in which the gate, source and drain lie. Usually the body terminal is connected to the highest or lowest voltage within the circuit, depending on type. The body terminal and the source terminal are sometimes connected together since the source is also sometimes connected to the highest or lowest voltage within the circuit, however there are several uses of FETs which do not have such a configuration, such as transmission gates and cascode circuits

FET operation

The FET controls the flow of electrons (or electron holes) from the source to drain by affecting the size and shape of a "conductive channel" created and influenced by voltage (or lack of voltage) applied across the gate and source terminals. (For ease of discussion, this assumes body and source are connected). This conductive channel is the "stream" through which electrons flow from source to drain.

Consider an **n-channel "depletion-mode" device**. A negative gate-to-source voltage causes a *depletion region* to expand in width and encroach on the channel from the sides, narrowing the channel. If the depletion region expands to completely close the channel, the resistance of the channel from source to drain becomes large, and the FET is effectively turned off like a switch. Likewise a positive gate-to-source voltage increases the channel size and allows electrons to flow easily.

Now consider an **n-channel "enhancement-mode" device**. A positive gate-to-source voltage is necessary to create a conductive channel, since one does not exist naturally within the transistor. The positive voltage attracts free-floating electrons within the body towards the gate, forming a conductive channel. But first, enough electrons must be attracted near the gate to counter the dopant ions added to the body of the FET; this forms a region free of mobile carriers called a depletion region, and the phenomenon is referred to as the *threshold voltage* of the FET. Further gate-to-source voltage increase will attract even more electrons towards the gate which are able to create a conductive channel from source to drain; this process is called *inversion*.

For either enhancement- or depletion-mode devices, at drain-to-source voltages much less than gate-to-source voltages, changing the gate voltage will alter the channel resistance, and drain current will be proportional to drain voltage (referenced to source voltage). In this mode the FET operates like a variable resistor and the FET is said to be operating in a *linear mode* or *ohmic mode*.[1][2]

If drain-to-source voltage is increased, this creates a significant asymmetrical change in the shape of the channel due to a gradient of voltage potential from source to drain. The shape of the inversion region becomes "pinched-off" near the drain end of the channel. If drain-to-source voltage is increased further, the pinch-off point of the channel begins to move away from the drain towards the source. The FET is said to be in *saturation mode*;[3] some authors refer to it as *active mode*, for a better analogy with bipolar transistor operating regions.[4][5] The saturation mode, or the region between ohmic and saturation, is used when amplification is needed. The in-between region is sometimes considered to be part of the ohmic or linear region, even where drain current is not approximately linear with drain voltage.

Even though the conductive channel formed by gate-to-source voltage no longer connects source to drain during saturation mode, carriers are not blocked from flowing. Considering again an n-channel device, a depletion region exists in the p-type body, surrounding the conductive channel and drain and source regions. The electrons which comprise the channel are free to move out of the channel through the depletion region if attracted to the drain by drain-to-source voltage. The depletion region is free of carriers and has a resistance similar to silicon. Any increase of the drain-to-source voltage will increase the distance from drain to the pinch-off point, increasing resistance due to the depletion region proportionally to the applied drain-to-source voltage. This proportional change causes the drain-to-source current to remain relatively fixed independent of changes to the drain-to-source voltage and quite unlike the linear mode operation. Thus in saturation mode, the FET behaves as a constant-current source rather than as a resistor and can be used most effectively as a voltage amplifier. In this case, the gate-to-source voltage determines the level of constant current through the channel.

Uses

The most commonly used FET is the MOSFET. The CMOS (complementary-symmetry metal oxide semiconductor) process technology is the basis for modern digital integrated circuits. This process technology uses an arrangement where the (usually "enhancement-mode") p-channel MOSFET and n-channel MOSFET are connected in series such that when one is on, the other is off.

The fragile insulating layer of the MOSFET between the gate and channel makes it vulnerable to electrostatic damage during handling. This is not usually a problem after the device has been installed.

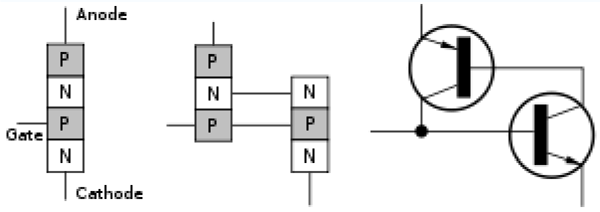
In FETs electrons can flow in either direction through the channel when operated in the linear mode, and the naming convention of drain terminal and source terminal is somewhat arbitrary, as the devices are typically (but not always) built symmetrically from source to drain. This makes FETs suitable for switching analog signals between paths (multiplexing). With this concept, one can construct a solid-state mixing board, for example.

Silicon-controlled rectifier (SCR)

A **silicon-controlled rectifier** (or **semiconductor-controlled rectifier**) is a four-layer solid state device that controls current. The name "silicon controlled rectifier" or **SCR** is General Electric's trade name for a type of thyristor. The SCR was developed by a team of power engineers led by Gordon Hall and commercialised by Frank W. "Bill" Gutzwiller in 1957.

Theory of operation

An SCR is a type of rectifier, controlled by a logic gate signal. It is a four-layer, three-terminal device. A p-type layer acts as an anode and an n-type layer as a cathode; the p-type layer closer to the n-type(cathode) acts as a gate.



An SCR (left) can be thought of as two BJT's working together (right).

Modes of operation

In the normal "off" state, the device restricts current to the leakage current. When the gate to cathode voltage exceeds a certain threshold, the device turns "on" and conducts current. The device will remain in the "on" state even after gate current is removed so long as current through the device remains above the holding current. Once current falls below the holding current for an appropriate period of time, the device will switch "off".

If the applied voltage increases rapidly enough, capacitive coupling may induce enough charge into the gate to trigger the device into the "on" state; this is referred to as "dv/dt triggering." This is usually prevented by limiting the rate of voltage rise across the device, perhaps by using a snubber. "dv/dt triggering" may not switch the SCR into full conduction rapidly and the partially-triggered SCR may dissipate more power than is usual, possibly harming the device.

SCRs can also be triggered by increasing the forward voltage beyond their rated breakdown voltage (also called as breakover voltage), but again, this does not rapidly switch the entire device into conduction and so may be harmful so this mode of operation is also usually avoided. Also, the actual breakdown voltage may be substantially higher than the rated breakdown voltage, so the exact trigger point will vary from device to device.

SCRs are made with voltage ratings of up to 7500 volts, and with current ratings up to 3000 RMS amperes per device. Some of the larger ones can take over 50 kA in single-pulse operation. SCRs are used in power switching, phase control, chopper, battery chargers, and inverter circuits. Industrially they are applied to produce variable DC voltages for motors (from a few to several thousand HP) from AC line voltage. They control the bulk of the dimmers used in stage lighting, and can also be used in some electric vehicles to modulate the working voltage in a Jacobson circuit. Another common application is phase control circuits used with inductive loads. SCRs can also be found in welding power supplies where they are used to maintain a constant output current or voltage. Large silicon-controlled rectifer assemblies with many individual devices connected in series are used in high-voltage DC converter stations.

Two SCRs in "inverse parallel" are often used in place of a TRIAC for switching inductive loads on AC circuits. Because each SCR only conducts for half of the power cycle and is reverse-biased for the other half-cycle, turn-off of the SCRs is assured. By comparison, the TRIAC is capable of conducting current in both directions and assuring that it switches "off" during the brief zero-crossing of current can be difficult.

Typical electrostatic discharge (ESD) protection structures in integrated circuits produce a parasitic SCR. This SCR is undesired; if it is triggered by accident, the IC can go into latchup and potentially be destroyed

TRIAC

A **TRIAC**, or **TRIode for Alternating Current** is an electronic component approximately equivalent to two silicon-controlled rectifiers (SCRs/thyristors) joined in inverse parallel (paralleled but with the polarity reversed) and with their gates connected together. Formal name for a TRIAC is **bidirectional triode thyristor**. This results in a bidirectional electronic switch which can conduct current in either direction when it is triggered (turned on). And thus doesn't have any polarity. It can be triggered by either a positive or a negative voltage being applied to its *gate* electrode (with respect to A1, otherwise known as MT1). Once triggered, the device continues to conduct until the current through it drops below a certain threshold value, such as at the end of a half-cycle of alternating current (AC) mains power. This makes the TRIAC a very convenient switch for AC circuits, allowing the control of very large power flows with milliampere-scale control currents. In addition, applying a trigger pulse at a controllable point in an AC cycle allows one to control the percentage of current that flows through the TRIAC to the load (so-called *phase control*).

Low power TRIACs are used in many applications such as light dimmers, speed controls for electric fans and other electric motors, and in the modern computerized control circuits of many household small

and major appliances. However, when used with inductive loads such as electric fans, care must be taken to assure that the TRIAC will turn off correctly at the end of each half-cycle of the ac power.

A snubber circuit is often used to assist this turn off. Snubber circuits are also used to prevent premature triggering. For higher-powered, more-demanding loads, two SCRs in inverse parallel may be used instead of one TRIAC. Because each SCR will have an entire half-cycle of reverse polarity voltage applied to it, turn-off of the SCRs is assured, no matter what the character of the load.

DIAC

The **DIAC**, or **diode for alternating current**, is a bidirectional trigger diode that conducts current only after its breakdown voltage has been exceeded momentarily. When this occurs, the resistance of the diode abruptly decreases, leading to a sharp decrease in the voltage drop across the diode and, usually, a sharp increase in current flow through the diode. The diode remains "in conduction" until the current flow through it drops below a value characteristic for the device, called the holding current. Below this value, the diode switches back to its high-resistance (non-conducting) state. When used in AC applications this automatically happens when the current reverses polarity.

Typical Diac voltage and current relationships. Once the voltage exceeds the turn-on threshold, the device turns on and the voltage rapidly falls while the current increases.

The behavior is typically the same for both directions of current flow. Most DIACs have a breakdown voltage around 30 V. In this way, their behavior is somewhat similar to (but much more precisely controlled and taking place at lower voltages than) a neon lamp.

DIACs are a form of thyristor but without a gate electrode. They are typically used for triggering both thyristors and TRIACs - a bidirectional member of the thyristor family. Because of this common usage, many TRIACs contain a built-in DIAC in series with the TRIAC's "gate" terminal.

DIACs are also called *symmetrical trigger diodes* due to the symmetry of their characteristic curve. Because DIACs are bidirectional devices, their terminals are not labeled as *anode* or *cathode* but as A1 and A2 or MT1 ("Main Terminal") and MT2.

Analog

The MOSFET's advantages in most digital circuits do not translate into supremacy in all analog circuits. The two types of circuit draw upon different features of transistor behavior. Digital circuits switch, spending most of their time outside the switching region, while analog circuits depend on MOSFET behavior held precisely in the switching region of operation. The bipolar junction transistor (BJT) has traditionally been the analog designer's transistor of choice, due largely to its higher transconductance and its higher output impedance (drain-voltage independence) in the switching region.

Nevertheless, MOSFETs are widely used in many types of analog circuits because of certain advantages. The characteristics and performance of many analog circuits can be designed by changing the sizes (length and width) of the MOSFETs used. By comparison, in most bipolar transistors the size of the device does not significantly affect the performance. MOSFETs' ideal characteristics regarding gate current (zero) and drain-source offset voltage (zero) also make them nearly ideal switch elements, and also make switched capacitor analog circuits practical. In their linear region, MOSFETs can be used as precision resistors, which can have a much higher controlled resistance than BJTs. In high power circuits, MOSFETs sometimes have the advantage of not suffering from thermal runaway as BJTs do. Also, they can be formed into capacitors and gyrator circuits which allow op-amps made from them to appear as inductors, thereby allowing all of the normal analog devices, except for diodes (which can be made smaller than a MOSFET anyway), to be built entirely out of MOSFETs. This allows for complete analog circuits to be made on a silicon chip in a much smaller space.

Some ICs combine analog and digital MOSFET circuitry on a single mixed-signal integrated circuit, making the needed board space even smaller. This creates a need to isolate the analog circuits from the digital circuits on a chip level, leading to the use of isolation rings and Silicon-On-Insulator (SOI). The main advantage of BJTs versus MOSFETs in the analog design process is the ability of BJTs to handle a larger current in a smaller space. Fabrication processes exist that incorporate BJTs and MOSFETs into a single device. Mixed-transistor devices are called Bi-FETs (Bipolar-FETs) if they contain just one BJT-FET and BiCMOS (bipolar-CMOS) if they contain complementary BJT-FETs. Such devices have the advantages of both insulated gates and higher current density.

BJTs have some advantages over MOSFETs for at least two digital applications. Firstly, in high speed switching, they do not have the "larger" capacitance from the gate, which when multiplied by the resistance of the channel gives the intrinsic time constant of the process. The intrinsic time constant places a limit on the speed a MOSFET can operate at because higher frequency signals are filtered out. Widening the channel reduces the resistance of the channel, but increases the capacitance by the exact same amount. Reducing the width of the channel increases the resistance, but reduces the capacitance by the same amount. R*C=Tc1, 0.5R*2C=Tc1, 2R*0.5C=Tc1. There is no way to minimize the intrinsic time constant for a certain process. Different processes using different channel lengths, channel heights, gate thicknesses and materials will have different intrinsic time constants. This problem is mostly avoided with a BJT because it does not have a gate.

The second application where BJTs have an advantage over MOSFETs stems from the first. When driving many other gates, called fanout, the resistance of the MOSFET is in series with the gate capacitances of the other FETs, creating a secondary time constant. Delay circuits use this fact to create a fixed signal delay by using a small CMOS device to send a signal to many other, many times larger

CMOS devices. The secondary time constant can be minimized by increasing the driving FET's channel width to decrease its resistance and decreasing the channel widths of the FETs being driven, decreasing their capacitance. The drawback is that it increases the capacitance of the driving FET and increases the resistance of the FETs being driven, but usually these drawbacks are a minimal problem when compared to the timing problem. BJTs are better able to drive the other gates because they can output more current than MOSFETs, allowing for the FETs being driven to charge faster. Many chips use MOSFET inputs and BiCMOS (see above) outputs.

Digital

The growth of digital technologies like the microprocessor has provided the motivation to advance MOSFET technology faster than any other type of silicon-based transistor. A timeline can be found at computerhistory.org.[21] A big advantage of MOSFETs for digital switching is that the oxide layer between the gate and the channel prevents DC current from flowing through the gate, further reducing power consumption and giving a very large input impedance. The insulating oxide between the gate and channel effectively isolates a MOSFET in one logic stage from earlier and later stages, which allows a single MOSFET output to drive a considerable number of MOSFET inputs. Bipolar transistor-based logic (such as TTL) does not have such a high fanout capacity. This isolation also makes it easier for the designers to ignore to some extent loading effects between logic stages independently. That extent is defined by the operating frequency: as frequencies increase, the input impedance of the MOSFETs decreases.

CMOS

The principal reason for the success of the MOSFET was the development of digital CMOS logic, which uses p- and n-channel MOSFETs as building blocks. Overheating is a major concern in integrated circuits since ever more transistors are packed into ever smaller chips. CMOS logic reduces power consumption because no current flows (ideally), and thus no power is consumed, except when the inputs to logic gates are being switched. CMOS accomplishes this current reduction by complementing every nMOSFET with a pMOSFET and connecting both gates and both drains together. A high voltage on the gates will cause the nMOSFET to conduct and the pMOSFET not to conduct and a low voltage on the gates causes the reverse. During the switching time as the voltage goes from one state to another, both MOSFETs will conduct briefly. This arrangement greatly reduces power consumption and heat generation. Digital and analog CMOS applications are described below.

The 8-pin 555 timer must be one of the most useful ICs ever made and it is used in many projects. With just a few external components it can be used to build many circuits, not all of them involve timing!

A popular version is the NE555 and this is suitable in most cases where a '555 timer' is specified. The 556 is a dual version of the 555 housed in a 14-pin package, the two timers (A and B) share the same power supply pins. The circuit diagrams on this page show a 555, but they could all be adapted to use one half of a 556.

Low power versions of the 555 are made, such as the ICM7555, but these should only be used when specified (to increase battery life) because their maximum output current of about 20mA (with a 9V supply) is too low for many standard 555 circuits. The ICM7555 has the same pin arrangement as a standard 555.

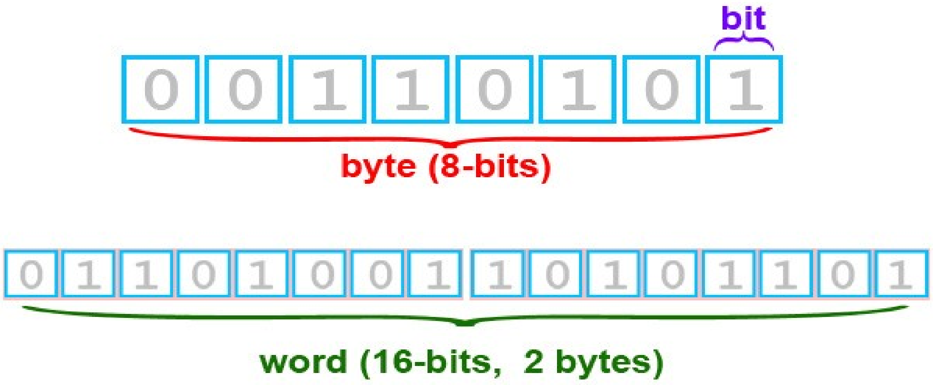
The circuit symbol for a 555 (and 556) is a box with the pins arranged to suit the circuit diagram: for example 555 pin 8 at the top for the +Vs supply, 555 pin 3 output on the right. Usually just the pin numbers are used and they are not labelled with their function.

The 555 and 556 can be used with a supply voltage (Vs) in the range 4.5 to 15V (18V absolute maximum).

Standard 555 and 556 ICs create a significant 'glitch' on the supply when their output changes state. This is rarely a problem in simple circuits with no other ICs, but in more complex circuits a **smoothing capacitor** (eg 100µF) should be connected across the +Vs and 0V supply near the 555 or 556.

The input and output pin functions are described briefly below and there are fuller explanations covering the various circuits:

BIT



A **bit** or **binary digit** is the basic unit of information in computing and telecommunications. The two values can also be interpreted as logical values (*true*/*false*, *yes*/*no*), algebraic signs (+/−), activation states (*on*/*off*), or any other two-valued attribute. In several popular programming languages, numeric 0 is equivalent (or convertible) to logical *false*, and 1 to *true*.

There are several units of information which are defined as multiples of bits, such as byte (8 bits), kilobit (either 1000 or 2^{10} = 1024 bits), megabyte (either 8000000 or 8×2^{20} = 8388608bits), etc.

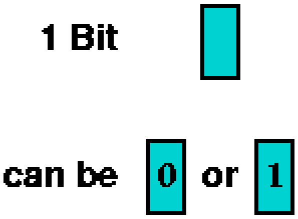
Byte

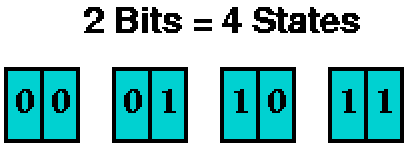
Binary Arithmetic

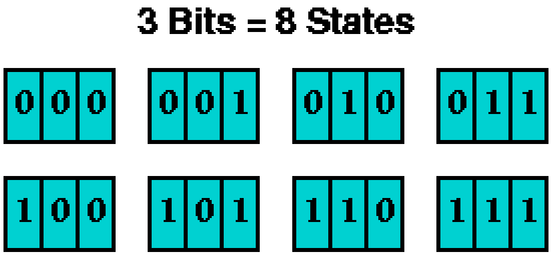
For some important aspects of Internet engineering, most notably IP Addressing, an understanding of binary arithmetic is critical. Many strange-looking decimal numbers can only be understood by converting them (at least mentally) to binary.

All digital computers represent data as a collection of *bits*. A bit is the smallest possible unit of information. It can be in one of two states - off or on, 0 or 1. The meaning of the bit, which can represent almost anything, is unimportant at this point. The thing to remember is that *all* computer data - a text file on disk, a program in memory, a packet on a network - is ultimately a collection of bits.

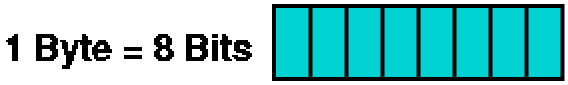


If one bit has two different states, how many states do two bits have? The answer is four. Likewise, three bits have eight states. For example, if a computer display had eight colors available, and you wished to select one of these to draw a diagram in, three bits would be sufficient to represent this information. Each of the eight colors would be assigned to one of the three-bit combinations. Then, you could pick one of the colors by picking the right three-bit combination.

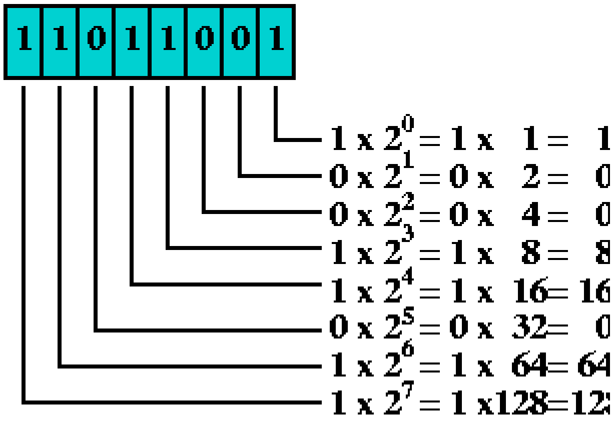




A common and convenient grouping of bits is the *byte* or *octet*, composed of eight bits. If two bits have four combinations, and three bits have eight combinations, how many combinations do eight bits have? If you don't want to write out all the possible byte patterns, just multiply eight twos together - one two for each bit. Two times two is four, so the number of combinations of two bits is four. Two times two times two is eight, so the number of combinations of three bits is eight. Do this eight times - or just compute two to the eighth power - and you discover that a byte has 256 possible states.



Obviously, if a byte has 256 possible states, its exact state can be represented by a number from 1 to 256. However, since zero is a very important number, a byte is more typically represented by a number from 0 to 255. This is very common, and with bit pattern 00000000 representing zero, and bit pattern 11111111 representing 255. The numbers matching these two patterns, and everything in between, can be computed by assigning a weight to each bit, multiplying each bit's value (0 or 1) by its weight, and then adding the totals. For example, here's how 217 is represented as 11011001 in binary:



$$1 + 8 + 16 + 64 + 128 = 217$$

To convert a number from decimal to binary, begin at leftmost bit position (128). If the number is larger than or equal to the bit's weight, write a 1 in the bit position, subtract the bit's weight from the number, and continue with the difference. If the number is less than the bit's weight, write a 0 in the bit position and continue without any subtraction. Here's an illustration of converting 141 to binary:

There is a simpler way to convert bytes back and forth between binary and decimal; akin to memorizing multiplication tables. The byte can split into two four-bit halves, each half called a *nibble*. Memorize the decimal values for the high nibble (they're just the multiples of 16). The low nibble is trivial. Every number between 0 and 255 is the sum of one of the high nibble values and one of the low nibble values. Write the high nibble next to the low nibble, and you have the byte value in binary. Conversely, an eight-bit binary byte can be split in half, each nibble converted to decimal and two decimal numbers added together.

Nibble

In computing, a **nibble** (often, **nybble**, or even **nyble** to simulate the spelling of **byte**) is a four-bit aggregation,[1] or half an octet. As a nibble contains 4 bits, there are sixteen (2^4) possible values, so a nibble corresponds to a single hexadecimal digit (thus, it is often referred to as a "hex digit" or "hexit")A full byte (octet) is represented by two hexadecimal digits; therefore, it is common to display a byte of information as two nibbles. The nibble is often called a "semioctet" or a "quartet" in a networking or telecommunication context. Sometimes the set of all 256 byte values is represented as a table 16×16, which gives easily readable hexadecimal codes for each value.

Logic gate

A **logic gate** performs a logical operation on one or more logic inputs and produces a single logic output. The logic normally performed is Boolean logic and is most commonly found in digital circuits.

Logic gates are primarily implemented electronically using diodes or transistors, but can also be constructed using electromagnetic relays, fluidics, optics, molecules, or even mechanical elements.

In electronic logic, a logic level is represented by a voltage or current, (which depends on the type of electronic logic in use). Each logic gate requires power so that it can source and sink currents to achieve the correct output voltage. In logic circuit diagrams the power is not shown, but in a full electronic schematic, power connections are required

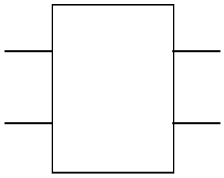
Flip-flop

In digital circuits, a flip-flop is a term referring to an electronic circuit (a bistable multivibrator) that has two stable states and thereby is capable of serving as one bit of memory. Today, the term flip-flop has come to mostly denote non-transparent (clocked or edge-triggered) devices, while the simpler transparent ones are often referred to as latches; however, as this distinction is quite new, the two words are sometimes used interchangeably (see history).

A flip-flop is usually controlled by one or two control signals and/or a gate or clock signal. The output often includes the complement as well as the normal output. As flip-flops are implemented electronically, they require power and ground connections.

Set-Reset flip-flops (SR flip-flops)



The symbol for an SR latch

The fundamental latch is the simple SR flip-flop , where S and R stand for set and reset respectively. It can be constructed from a pair of cross-coupled NOR logic gates. The stored bit is present on the output marked Q.

Normally, in storage mode, the S and R inputs are both low, and feedback maintains the Q and Q outputs in a constant state, with Q the complement of Q. If S (Set) is pulsed high while R is held low, then the Q output is forced high, and stays high even after S returns low; similarly, if R (Reset) is pulsed high while S is held low, then the Q output is forced low, and stays low even after R returns low.

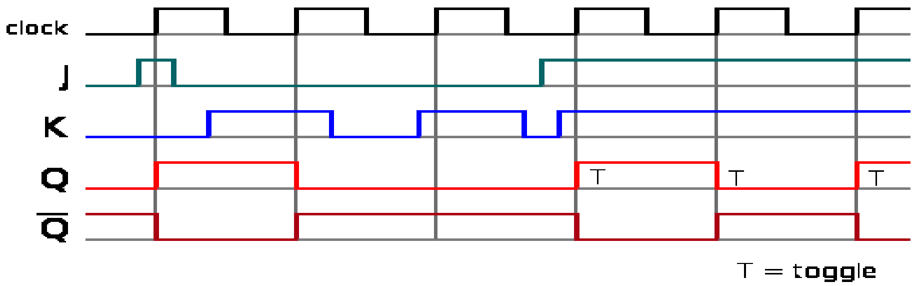
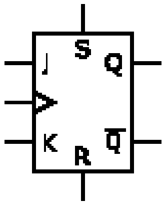
JK flip-flop



JK flip-flop timing diagram

The JK flip-flop augments the behavior of the SR flip-flop (J=Set, K=Reset) by interpreting the S = R = 1 condition as a "flip" or toggle command. Specifically, the combination J = 1, K = 0 is a command to set the flip-flop; the combination J = 0, K = 1 is a command to reset the flip-flop; and the combination J = K = 1 is a command to toggle the flip-flop, i.e., change its output to the logical complement of its current value. Setting J = K = 0 does NOT result in a D flip-flop, but rather, will hold the current state. To synthesize a D flip-flop, simply set K equal to the complement of J. The JK flip-flop is therefore a universal flip-flop, because it can be configured to work as an SR flip-flop, a D flip-flop, or a T flip-flop. NOTE: The flip flop is positive edge triggered (Clock Pulse) as seen in the timing diagram.



A circuit symbol for a JK flip-flop, where > is the clock input, J and K are data inputs, Q is the stored data output, and Q' is the inverse of Q.

The characteristic equation of the JK flip-flop is:

$$Q_{next} = J\overline{Q} + \overline{K}Q$$

and the corresponding truth table is:

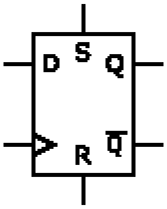
D flip-flop



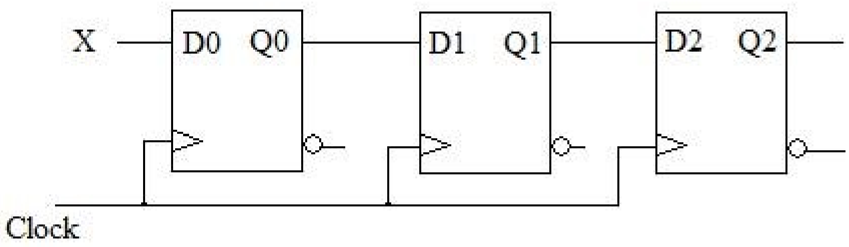
D flip-flop symbol

The Q output always takes on the state of the D input at the moment of a rising clock edge (or falling edge if the clock input is active low). It is called the D flip-flop for this reason, since the output takes the value of the D input or Data input, and Delays it by one clock count. The D flip-flop can be interpreted as a primitive memory cell, zero-order hold, or delay line.

Truth table:

Clock	D	Q	Qprev
Rising edge	0	0	X
Rising edge	1	1	X
Non-Rising	X	Qprev	

('X' denotes a Don't care condition, meaning the signal is irrelevant)



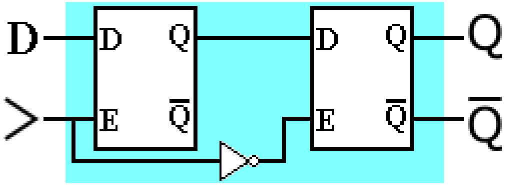
3-bit shift register

These flip flops are very useful, as they form the basis for shift registers, which are an essential part of many electronic devices. The advantage of the D flip-flop over the D-type latch is that it "captures" the signal at the moment the clock goes high, and subsequent changes of the data line do not influence Q until the next rising clock edge. An exception is that some flip-flops have a 'reset' signal input, which will reset Q (to zero), and may be either asynchronous or synchronous with the clock.

The above circuit shifts the contents of the register to the right, one bit position on each active transition of the clock. The input X is shifted into the leftmost bit position.

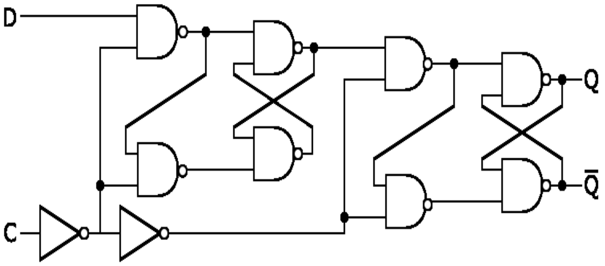
Master-slave (pulse-triggered) D flip-flop

A master-slave D flip-flop is created by connecting two gated D latches in series, and inverting the enable input to one of them. It is called master-slave because the second latch in the series only changes in response to a change in the first (master) latch. The term pulse triggered means that data are entered on the rising edge of the clock pulse, but the output doesn't reflect the change until the falling edge of the clock pulse.



A master slave D flip flop. It responds on the negative edge of the enable input (usually a clock).

For a positive-edge triggered master-slave D flip-flop, when the clock signal is low (logical 0) the “enable” seen by the first or “master” D latch (the inverted clock signal) is high (logical 1). This allows the “master” latch to store the input value when the clock signal transitions from low to high. As the clock signal goes high (0 to 1) the inverted “enable” of the first latch goes low (1 to 0) and the value seen at the input to the master latch is “locked”. Nearly simultaneously, the twice inverted “enable” of the second or “slave” D latch transitions from low to high (0 to 1) with the clock signal. This allows the signal captured at the rising edge of the clock by the now “locked” master latch to pass through the “slave” latch. When the clock signal returns to low (1 to 0), the output of the "slave" latch is "locked", and the value seen at the last rising edge of the clock is held while the “master” latch begins to accept new values in preparation for the next rising clock edge.



An implementation of a master-slave D flip-flop that is triggered on the positive edge of the clock.

By removing the left-most inverter in the above circuit, a D-type flip flop that strobes on the falling edge of a clock signal can be obtained. This has a truth table like this:

D	Q	>	Qnext
0	X	Falling	0
1	X	Falling	1

Most D-type flip-flops in ICs have the capability to be set and reset, much like an SR flip-flop. Usually, the illegal S = R = 1 condition is resolved in D-type flip-flops.

Inputs				Outputs	
S	R	D	>	Q	Q'
0	1	X	X	0	1
1	0	X	X	1	0
1	1	X	X	1	1

By setting S = R = 0, the flip-flop can be used as described above.

Edge-triggered D flip-flop

A more efficient way to make a D flip-flop is not so easy to understand, but it works the same way. While the master-slave D flip flop is also triggered on the edge of a clock, its components are each triggered by clock levels. The "edge-triggered D flip flop" does not have the master slave properties.

How to Solder

Soldering Advice for Components

It is very tempting to start soldering components onto the circuit board straight away, but please take time to identify all the parts first. You are much less likely to make a mistake if you do this!

1. **Stick all the components onto a sheet of paper using sticky tape.**
2. **Identify each component** and write its name or value beside it.
3. **Add the code (R1, R2, C1 etc.) if necessary.** Many projects from books and magazines label the components with codes (R1, R2, C1, D1 etc.) and you should use the project's parts list to find these codes if they are given.
4. **Resistor values** can be found using the resistor colour code which is explained on our Resistors page. You can print out and make your own Resistor Colour Code Calculator to help you.
5. **Capacitor values** can be difficult to find because there are many types with different labelling systems! The various systems are explained on our Capacitors page.

Some components require special care when soldering. Many must be placed the correct way round and a few are easily damaged by the heat from soldering. Appropriate warnings are given in the table below, together with other advice which may be useful when soldering.

For most projects it is best to put the components onto the board in the order given below:

	Components	Pictures	Reminders and Warnings
1	**IC Holders** (DIL sockets)		**Connect the correct way round** by making sure the notch is at the correct end. Do NOT put the ICs (chips) in yet.
2	**Resistors**		No special precautions are needed with resistors.

3	**Small value capacitors** (usually less than 1µF)		These may be connected either way round. Take care with polystyrene capacitors because they are easily damaged by heat.
4	**Electrolytic capacitors** (1µF and greater)		**Connect the correct way round.** They will be marked with a + or - near one lead.
5	**Diodes**		**Connect the correct way round.** Take care with germanium diodes (e.g. OA91) because they are easily damaged by heat.
6	**LEDs**		**Connect the correct way round.** The diagram may be labelled **a** or **+** for anode and **k** or **-** for cathode; yes, it really is k, not c, for cathode! The cathode is the short lead and there may be a slight flat on the body of round LEDs.
7	**Transistors**		**Connect the correct way round.** Transistors have 3 'legs' (leads) so extra care is needed to ensure the connections are correct. Easily damaged by heat.
8	**Wire Links** between points on the circuit board.	 single core wire	Use single core wire, this is one solid wire which is plastic-coated. If there is no danger of touching other parts you can use tinned copper wire, this has no plastic coating and looks just like solder but it is stiffer.
9	**Battery clips**, **buzzers** and other parts with their own wires		**Connect the correct way round.**
10	**Wires** to parts off the circuit board, including **switches**, **relays**, **variable resistors** and **loudspeakers**.	 stranded wire	You should use stranded wire which is flexible and plastic-coated. Do not use single core wire because this will break when it is repeatedly flexed.
11	**ICs (chips)**		**Connect the correct way round.** **Many ICs are static sensitive.** Leave ICs in their antistatic packaging until you need them, then earth your hands by touching a metal water pipe or window frame before touching the ICs. **Carefully insert ICs in their holders**: make sure all the pins are lined up with the socket then push down firmly with your thumb.

CLASSIFICATION OF FLUXES

1. INORGANIX FLUX
2. ORGANIC FLUX
3. ROSIN BASED FLUX
4. NO CLEAN FLUX

1. INORGANIC FLUX:

Consist of mixture of salts/acids such as HCL, H3PO4, $Zncl_2$, Nh_4Cl, Na_2Bo, having picking action through generated HCI acid in contact with moisture or added water. These fluxes are very corrosive in nature and generally not used in electronic assemblies.

2. NON ROSIN BASED FLUXES

These fluxes do not contain Rosin but contain only activators based on GLIMTIC, LACTIC ACIDS/HYDROCHLORIDES, water soluble and meditatively corrosive, hence must be cleaned after soldering process thoroughly.

3. ROSIN BASED FLUXES

Rosin which is naturally available from pine a tree by tapping is made into crystalline structure with pale yellow to Dark brown colour is used as base.

Rosin is a mixture of several organic compounds like ABETIC ACID, PIMARIC ACID, etc., pure Rosin is a weak pickling agent. For heavier passivation layer, surface activators like Bromides/ chlorides are added. The acid contents for various R type of fluxes are given below.

R – ROSIN NON ACTIVATED.	ACID CONTENT: < 0.2%
RAM – ROSIN MILDLY ACTIVATED.	ACID CONTENT: 0.2% TO 0.4%
RA – ROSIN ACTIVATED.	ACID CONTENT: 0.4% to 4%
RSA – ROSIN SUPER ACTIVATED.	ACID CONTENT: > 4%

4. NO CLEAN FLUX

Does not contain natural Rosin but obtained by synthetic resins solvents, foaming agents and activators. Generally does not leave any residues.

1. SOLDER ALLOY

WHY TIN & LEAD

1. Tin is not appreciably affected by air or water.
2. The corrosion resistance of tin is an important factor for using as a coating on Copper wire to protect against corrosion.
3. Tin reacts and alloys with metal easily.
4. Lead is soft and dense, but surface gets quickly corroded.
5. Lead reduces the melting temperature and brittleness thus adding to the overall strength of alloy.

METALLURGY OF SOLDER JOINTS

When two metals “A” and “B” are soldered with a filler material “S”. The following regions occur in the final joint structure.

1. PURE “A”
2. ALLOY OF “A” AND “S”
3. PURE “S”
4. ALLOY OF “S” AND “B”
5. PURE “B”

The alloy region consists of irreversible compounds created out of the metals and the filler. The filler, the thickness of this alloy being 0.1 to 1.0 microns. This zone is usually called as intermetallic layer in case of Cu-Solder (sn-pb) combination. They are typically cu3sn, cu6sn5. This intermetallic layer is mainly responsible for the strength of the joint. This layer thickness increases with time and temperature of the soldering. This intermatellic layer is brittle in nature. Hence the thickness of this layer has to be controlled.

CHEMICAL COMPOSITION OF Sn63, Sn60

	Sn63	**Sn60**

What is solder?

Reels of solder

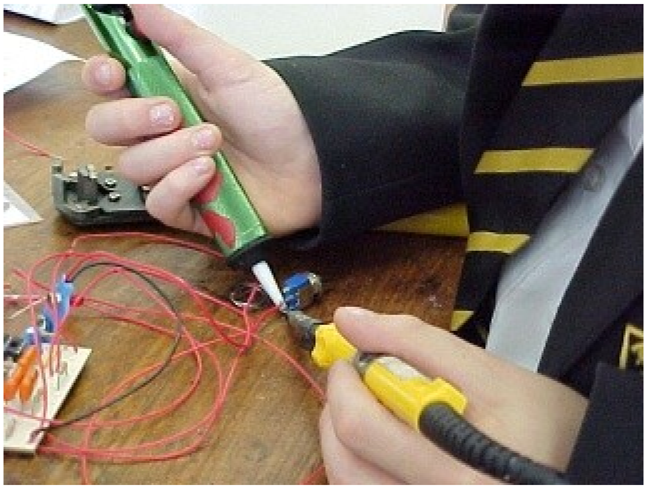
Solder is an alloy (mixture) of tin and lead, typically 60% tin and 40% lead. It melts at a temperature of about 200°C. Coating a surface with solder is called 'tinning' because of the tin content of solder. Lead is poisonous and you should always wash your hands after using solder.

Solder for electronics use contains tiny cores of flux, like the wires inside a mains flex. The flux is corrosive, like an acid, and it cleans the metal surfaces as the solder melts. This is why you must melt the solder actually on the joint, not on the iron tip. Without flux most joints would fail because metals quickly oxidise and the solder itself will not flow properly onto a dirty, oxidised, metal surface.

The best size of solder for electronics is 22swg (SWG= standard wire gauge).

Desoldering

At some stage you will probably need to desolder a joint to remove or re-position a wire or component. There are two ways to remove the solder:



Using a desoldering pump (solder sucker)

1. **With a desoldering pump (solder sucker)**

- Set the pump by pushing the spring-loaded plunger down until it locks.
- Apply both the pump nozzle and the tip of your soldering iron to the joint.
- Wait a second or two for the solder to melt.
- Then press the button on the pump to release the plunger and suck the molten solder into the tool.
- Repeat if necessary to remove as much solder as possible.
- The pump will need emptying occasionally by unscrewing the nozzle.

SOLDER REMOVER

Solder remover wick

2. **With solder remover wick (copper braid)**

- Apply both the end of the wick and the tip of your soldering iron to the joint.
- As the solder melts most of it will flow onto the wick, away from the joint.
- Remove the wick first, then the soldering iron.
- Cut off and discard the end of the wick coated with solder.

After removing most of the solder from the joint(s) you may be able to remove the wire or component lead straight away (allow a few seconds for it to cool). If the joint will not come apart easily apply your soldering iron to melt the remaining traces of solder at the same time as pulling the joint apart, taking care to avoid burning yourself.

Soldering iron

For electronics work the best type is one powered by mains electricity (230V in the UK), it should have a heatproof cable for safety. The iron's power rating should be 15 to 25W and it should be fitted with a small bit of 2 to 3mm diameter.

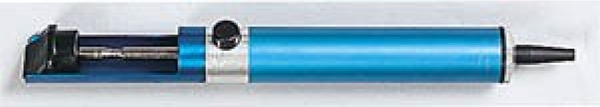
Other types of soldering iron

Low voltage soldering irons are available, but their extra safety is undermined if you have a mains lead to their power supply! **Temperature controlled** irons are excellent for frequent use, but not worth the extra expense if you are a beginner. **Gas-powered** irons are designed for use where no mains supply is available and are not suitable for everyday use. Pistol shaped **solder guns** are far too powerful and cumbersome for normal electronics use.

Soldering iron stand

You must have a safe place to put the iron when you are not holding it. The stand should include a sponge which can be dampened for cleaning the tip of the iron.

Desoldering pump (solder sucker)



A tool for removing solder when desoldering a joint to correct a mistake or replace a component.

Solder remover wick (copper braid)

This is an alternative to the desoldering pump shown above.

Reel of solder

The best size for electronics is 22swg
(SWG standardwire gauge).

Side cutters

For trimming component leads close to the circuit board.

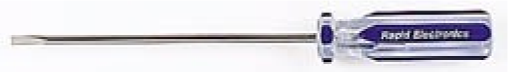
Wire strippers

Most designs include a cutter as suitable for trimming component leads.

Small pliers

Usually called 'snipe nose' pliers, these are for bending component leads etc. If you put a strong rubber band across the handles the pliers make a convenient holder for parts such as switches while you solder the contacts.

Small flat-blade screwdriver



For scraping away excess flux and dirt between tracks, as well as driving screws!

Heat sink

You can buy a special tool, but a standard crocodile clip works just as well and is cheaper.

The following tool is only required if you are using stripboard:

Track cutter

A 3mm drill bit can be used instead, in fact the tool is usually just a 3mm drill bit with a proper handle fitted.

The following tools are only required if you make your own PCBs:

PCB rubber

This is an abrasive rubber for cleaning PCBs. It can also be used to clean strip board where the copper tracks have become dull and tarnished.

Breadboard

A breadboard (solder less breadboard, protoboard, plug board) is reusable sometimes [1] solder less device used to build a (generally temporary) prototype of an electronic circuit and for experimenting with circuit designs. This is in contrast to strip board (Vero board) and similar prototyping printed circuit boards, which are used to build more permanent soldered prototypes or one-offs, and cannot easily be reused. A variety of electronic systems may be prototyped by using breadboards, from small analog and digital circuits to complete central processing units (CPUs).

The term breadboard is derived from an early form of point-to-point construction: in particular, the practice of constructing simple circuits (usually using valves/tubes) on a convenient wooden base, similar to a cutting board like the kind used for slicing bread with a knife. It can also be viewed as bread with a large number of pores (holes for connection); like the bread most commonly used in America and Europe, a modern prototyping board is typically white or off-white.

Jump wires

The jump wires for breadboarding can be obtained in ready-to-use jump wire sets or can be manually manufactured. The latter can become tedious work for larger circuits. Ready-to-use jump wires come in different qualities, some even with tiny plugs attached to the wire ends. Jump wire material for ready-made or home-made wires should usually be 22 AWG (0.33 mm²) solid copper, tin-plated wire - assuming no tiny plugs are to be attached to the wire ends. The wire ends should be stripped 3/16" to 5/16" (approx. 5 mm to 8 mm). Shorter stripped wires might result in bad contact with the board's spring clips (insulation being caught in the springs). Longer stripped wires increase the likelihood of short-circuits on the board. Needle-nose pliers and tweezers are helpful when inserting or removing wires, particularly on crowded boards.

Differently colored wires and color coding discipline are often adhered to for consistency. However, the number of available colors is typically far less than the number of signal types or paths. So typically a few wire colors get reserved for the supply voltages and ground (e.g. red, blue, black), some more for main signals, while the rest often get random colors. There are ready-to-use jump wire sets on the market where the color indicates the length of the wires; however, these sets do not allow applying a meaningful color coding schema.

Diagram

A "full size" terminal breadboard strip typically consists of around 56 to 65 rows of connectors, each row containing the above mentioned two sets of connected clips (A to E and F to J). "Small size" strips typically come with around 30 rows.

PCBs are boards whereupon electronic circuits have been etched. PCBs are rugged, inexpensive, and can be highly reliable. They require much more layout effort and higher initial cost than either wire-wrapped or point-to-point constructed circuits, but are much cheaper and faster for high-volume production. Much of the electronics industry's PCB design, assembly, and quality control needs are set by standards that are published by the IPC organization.

ELECTRONIC PRODUCTS

Consisting of electronic assemblies, a combination of electronic components and devices and PCBs. Components need to be interconnected for their functioning, to get the desired results.

Generally, these components are mounted on Printed wiring board which provides support and required interconnection.

ABOUT THE PCB

Printed wiring Board, an essential part of total electronic packaging system, which provides interconnection between components, and physical support for the whole assembly. Various types and configuration of components are mounted on Printed wiring board to make the board functional as an electronic device.

The printed wiring boards are classified as follows:

i. Single sided
ii. Double sided
iii. Multi layer
iv. Flexible

The single sided PCB is the simplest, and has the conductor pattern printed only on one side. The components are inserted and mounted on the other side of the PCB. The double sided PCB has conductor patterns on both sides and components are mounted on one side, while in a multilayer PCB has several layers of conductors which are sand witched together.

The PCB consists of conductor tracks of Solder plated copper and required size of Holes (or plated through holes) for mounting various components as per design.

The basic substrate for the PCBs is made up of one of the following insulating materials:

i. Paper phenol
ii. Glass epoxy
iii. Glass polyamide
iv. Ceramic

The flexible boards are generally made up of polyamide substrate.

The Ceramic substrate is generally used in Defense applications where the ceramic components are used.

SOLDER MASK: Solder mask is applied on the Bare printed Circuit board for avoiding solder coating on unwanted conductor tracks during wave soldering and preventing conductor tracks from exposing to atmosphere. Normal conformal coating materials are

1. Acrylic
2. Polyurethane
3. Silicone
4. Paraxylylene
5. Epoxy

These coatings are applied by means of dipping, spraying, brushing or vacuum deposition depending upon material used.

Surface-mount technology

Surface-mount technology (**SMT**) is a method for constructing electronic circuits in which the components (SMC or Surface Mounted Components) are mounted directly onto the surface of printed circuit boards (PCBs). Electronic devices so made are called *surface-mount devices* or **SMD**s. In the industry it has largely replaced the through-hole technology construction method of fitting components with wire leads into holes in the circuit board.

An SMT component is usually smaller than its through-hole counterpart because it has either smaller leads or no leads at all. It may have short pins or leads of various styles, flat contacts, a matrix of solder balls (BGAs), or terminations on the body of the component.

GETTING STARTED IN ELECTRONICS

WELCOME TO THE WORLD OF ELECTRONICS, ONE OF THE FASTEST GROWING OF TODAY'S "HIGH-TECH" FIELDS *AND* AN EDUCATIONAL AND ENTERTAINING HOBBY. THIS BOOK WILL TAKE YOU FROM STATIC ELECTRICITY TO SOLID-STATE ELECTRONICS. ALONG THE WAY WE'LL COVER ELECTRICITY, ELECTRONIC COMPONENTS AND INTEGRATED CIRCUITS (IC'S). CHAPTERS 3-7 SHOW HOW COMPONENTS AND IC'S ARE USED TO FORM ELECTRONIC CIRCUITS. CHAPTER 9 GIVES PLANS FOR 100 CIRCUITS, EACH OF WHICH I'VE BUILT AND TESTED. "PAGE ARROWS" (P.xx ⇨) THROUGHOUT THE BOOK REFER YOU TO RELATED TOPICS IN FUTURE CHAPTERS (LIKE WORKING VERSIONS OF MANY EXAMPLE CIRCUITS IN CHAPTERS 3-7). I HOPE YOU FIND THIS BOOK USEFUL, EDUCATIONAL AND, ESPECIALLY, FUN! Forrest M. Mims, III

GOING FURTHER IN ELECTRONICS

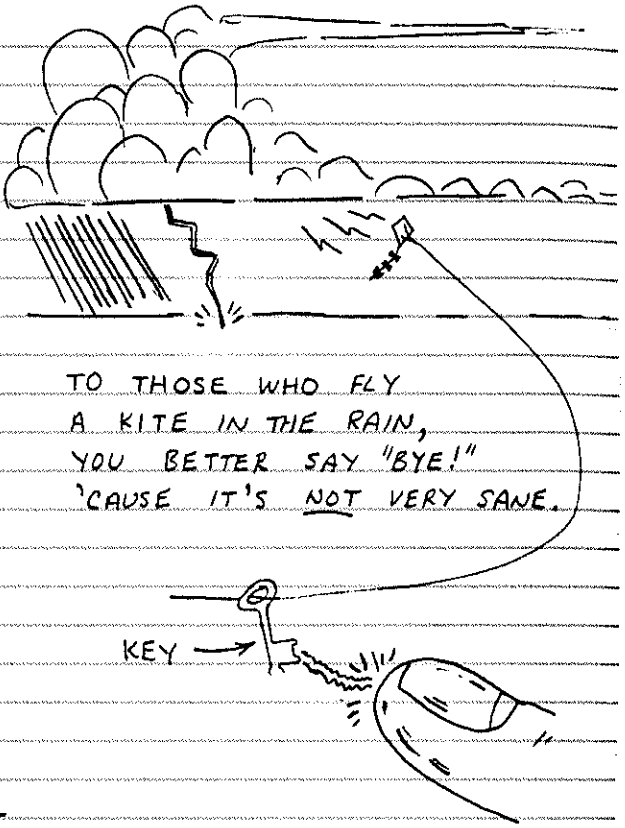
I HOPE THIS BOOK ENCOURAGES YOU TO GO FURTHER IN ELECTRONICS. BEGIN BY GETTING RADIO SHACK'S "SEMICONDUCTOR REFERENCE HANDBOOK" AND "ENGINEER'S MINI-NOTEBOOK" SERIES. READ ELECTRONICS MAGAZINES LIKE *COMPUTERCRAFT*, *RADIO-ELECTRONICS*, *BYTE* AND *QST*. YOU MAY ALSO WISH TO READ "ELECTRONICS NOTEBOOK," A COLUMN I WRITE EACH MONTH FOR *COMPUTERCRAFT*. MANY OF THESE COLUMNS HAVE BEEN COMPILED IN A SERIES OF BOOKS, INCLUDING "THE FORREST MIMS CIRCUIT SCRAPBOOK" (McGRAW-HILL, 1983) AND "FORREST MIMS' CIRCUIT SCRAPBOOK II (HOWARD W. SAMS, 1986). THESE BOOKS DESCRIBE IN DETAIL SEVERAL OF THE CIRCUITS IN *THIS* BOOK AND MANY OTHER CIRCUITS. QUESTIONS? THIS BOOK WILL RAISE MANY! IF YOU CAN'T FIND ANSWERS IN THE REFERENCES ABOVE, TRY A *GOOD* LIBRARY. FINDING ANSWERS MAY TAKE TIME, BUT YOU'LL LEARN MUCH IN THE PROCESS. PERHAPS YOU'LL EVEN CONSIDER FORMAL TRAINING FOR A CAREER IN ELECTRONICS.

A SPECIAL NOTE TO EDUCATORS

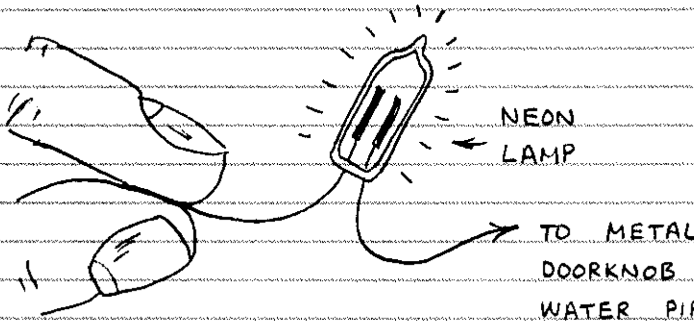
THIS BOOK CAN GIVE YOUR STUDENTS A BASIC KNOWLEDGE OF ELECTRONICS. YOU CAN ASSIGN THE BOOK FOR OUTSIDE READING AND TEST STUDENTS AS THEY PROGRESS. OR YOU CAN DEVELOP A TOTAL COURSE, COMPLETE WITH DEMONSTRATIONS, EXPERIMENTS AND LECTURES. THANKS TO RADIO SHACK'S SOLDERLESS MODULAR SOCKETS, YOU AND YOUR STUDENTS SHOULD BE ABLE TO ASSEMBLE TEST VERSIONS OF VIRTUALLY EVERY CIRCUIT IN CHAPTER 9 ("100 ELECTRONIC CIRCUITS"). INCIDENTALLY, VOLUME BUYERS CAN RECEIVE A PRICE DISCOUNT FROM RADIO SHACK ON THIS BOOK AND ELECTRONIC COMPONENTS. SEE THE LATEST RADIO SHACK CATALOG FOR DETAILS. (PRICE DISCOUNTS ARE OPTIONAL AT RADIO SHACK DEALERS AND FRANCHISE STORES.)

1. ELECTRICITY

THE ONLY DIFFERENCE BETWEEN A BOLT OF LIGHTNING AND THE SPARK BETWEEN YOUR FINGER AND A DOORKNOB ON A DRY DAY IS QUANTITY. BOTH ARE ELECTRICITY. BENJAMIN FRANKLIN FIRST CONFIRMED THIS WITH HIS FAMOUS KITE EXPERIMENT.

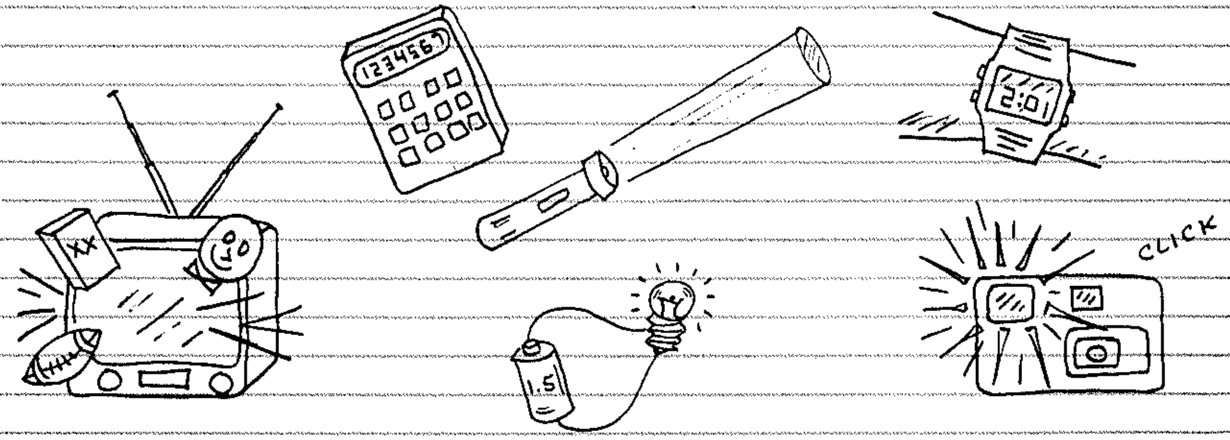


TO THOSE WHO FLY
A KITE IN THE RAIN,
YOU BETTER SAY "BYE!"
'CAUSE IT'S NOT VERY SANE.



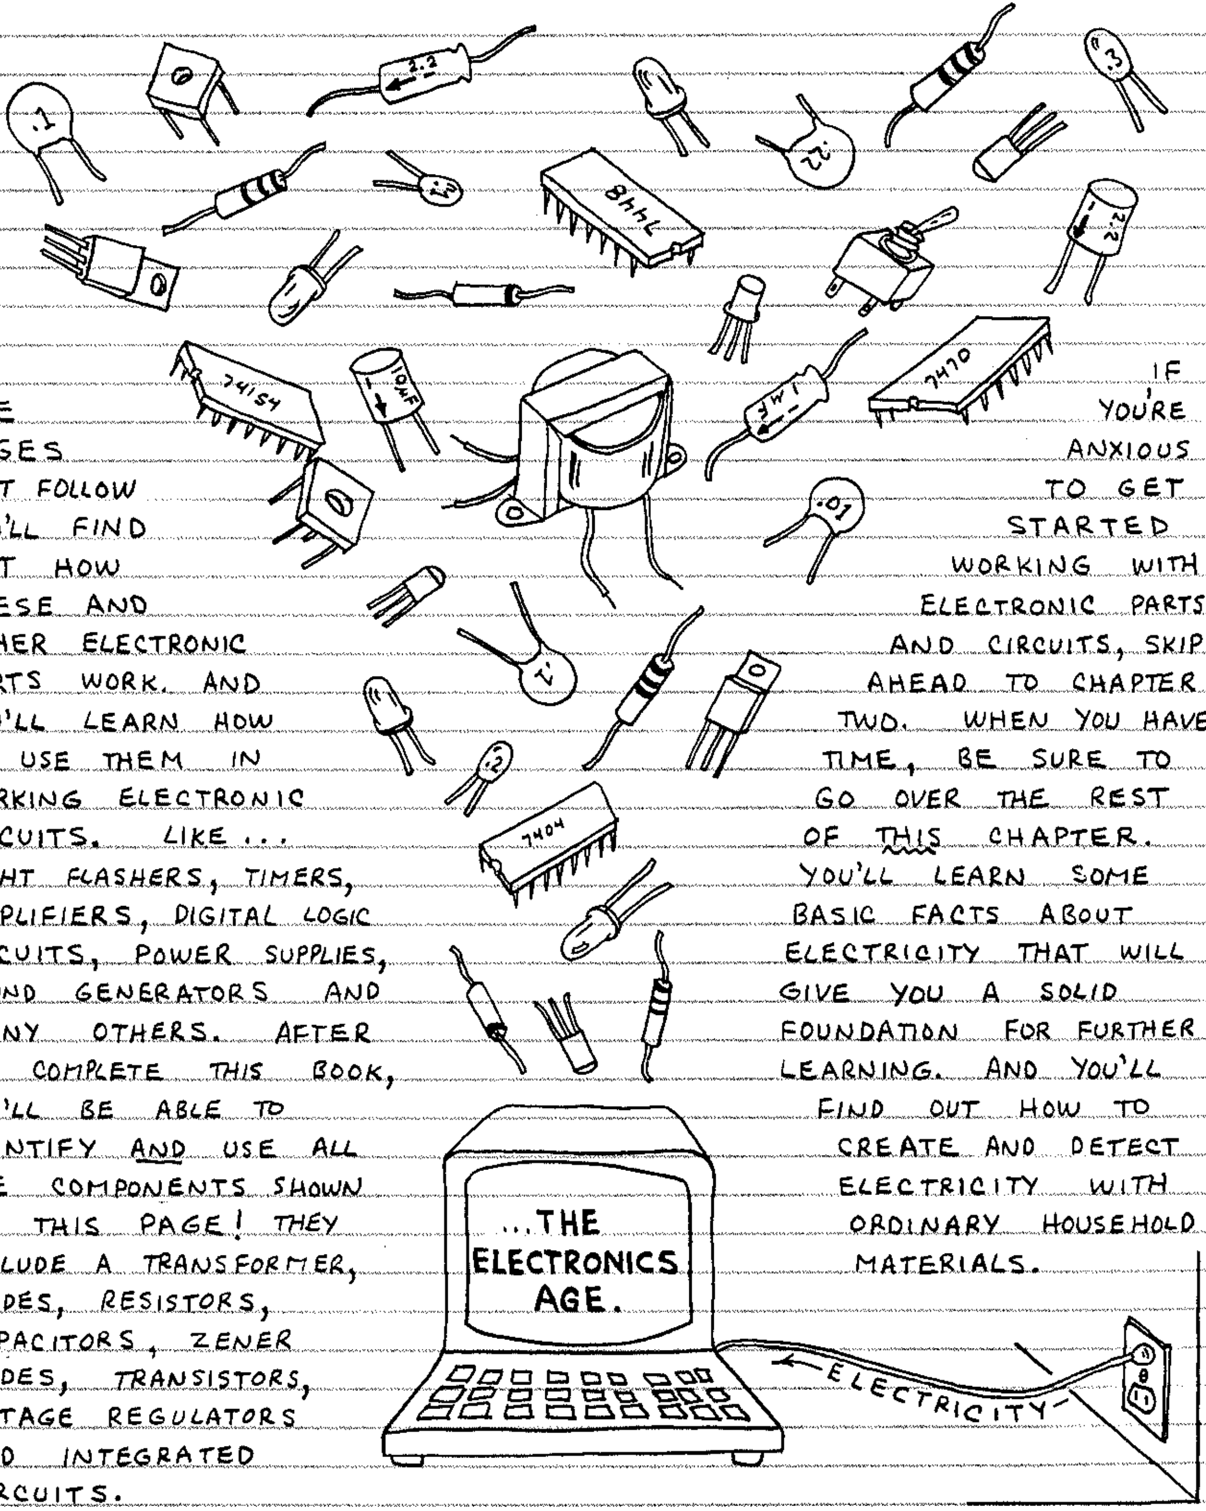
HERE'S A NEAT WAY TO "SEE" ELECTRICITY WITHOUT BEING ZAPPED: GRASP ONE LEAD FROM A NEON LAMP, WALK ACROSS A CARPET WHILE WEARING HARD SOLED SHOES AND TOUCH THE SECOND LEAD FROM THE LAMP TO A METAL OBJECT. THE LAMP WILL FLASH (UNLESS THE RELATIVE HUMIDITY IS HIGH).

OF COURSE, YOU CANNOT "SEE" ELECTRICITY! YOU SEE ITS EFFECT UPON AIR AND THE NEON IN THE LAMP. THE EFFECTS OF ELECTRICITY WHICH CAN BE SEEN ARE MANY. HERE ARE SOME MORE:



PUTTING ELECTRICITY TO WORK

ALL MATTER HAS ELECTRICAL PROPERTIES. THAT'S WHY SCIENTISTS OVER THE PAST FEW CENTURIES HAVE BEEN ABLE TO INVENT HUNDREDS OF GADGETS THAT GENERATE, STORE, CONTROL AND SWITCH ELECTRICITY. THESE DEVICES HAVE COMBINED TO CARRY US INTO...

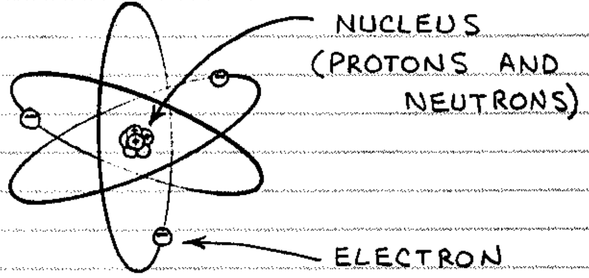


IN THE PAGES THAT FOLLOW YOU'LL FIND OUT HOW THESE AND OTHER ELECTRONIC PARTS WORK. AND YOU'LL LEARN HOW TO USE THEM IN WORKING ELECTRONIC CIRCUITS. LIKE... LIGHT FLASHERS, TIMERS, AMPLIFIERS, DIGITAL LOGIC CIRCUITS, POWER SUPPLIES, SOUND GENERATORS AND MANY OTHERS. AFTER YOU COMPLETE THIS BOOK, YOU'LL BE ABLE TO IDENTIFY AND USE ALL THE COMPONENTS SHOWN ON THIS PAGE! THEY INCLUDE A TRANSFORMER, DIODES, RESISTORS, CAPACITORS, ZENER DIODES, TRANSISTORS, VOLTAGE REGULATORS AND INTEGRATED CIRCUITS.

IF YOU'RE ANXIOUS TO GET STARTED WORKING WITH ELECTRONIC PARTS AND CIRCUITS, SKIP AHEAD TO CHAPTER TWO. WHEN YOU HAVE TIME, BE SURE TO GO OVER THE REST OF THIS CHAPTER. YOU'LL LEARN SOME BASIC FACTS ABOUT ELECTRICITY THAT WILL GIVE YOU A SOLID FOUNDATION FOR FURTHER LEARNING. AND YOU'LL FIND OUT HOW TO CREATE AND DETECT ELECTRICITY WITH ORDINARY HOUSEHOLD MATERIALS.

BACK TO BASICS

ELECTRICITY IS AN ESSENTIAL INGREDIENT OF MATTER. THE BEST WAY TO UNDERSTAND THE NATURE OF ELECTRICITY IS TO EXAMINE THE SMALLEST COMPONENT OF EVERY ELEMENT, THE ATOM.

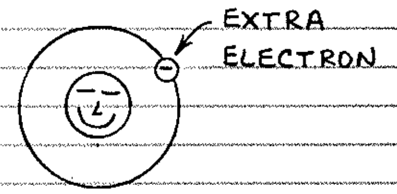


LITHIUM ATOM

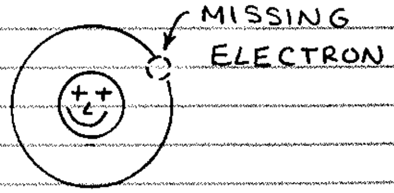
THIS IS A LITHIUM ATOM. THE THIRD SIMPLEST ATOM AFTER HYDROGEN AND HELIUM, LITHIUM ATOMS HAVE 3 ELECTRONS THAT ENCIRCLE A NUCLEUS OF 3 PROTONS AND 4 NEUTRONS.

⊖ ELECTRONS HAVE A NEGATIVE ELECTRICAL CHARGE.
⊕ PROTONS HAVE A POSITIVE ELECTRICAL CHARGE.
○ NEUTRONS HAVE NO ELECTRICAL CHARGE.

☐ IONS — NORMALLY AN ATOM HAS AN EQUAL NUMBER OF ELECTRONS AND PROTONS. THE CHARGES CANCEL TO GIVE THE ATOM NO NET ELECTRICAL CHARGE. IT'S POSSIBLE TO DISLODGE ONE OR MORE ELECTRONS FROM MOST ATOMS. THIS CAUSES THE ATOM TO HAVE A NET POSITIVE CHARGE. IT'S THEN CALLED A POSITIVE ION. IF A STRAY ELECTRON COMBINES WITH A NORMAL ATOM, THE ATOM HAS A NET NEGATIVE CHARGE AND IS CALLED A NEGATIVE ION.



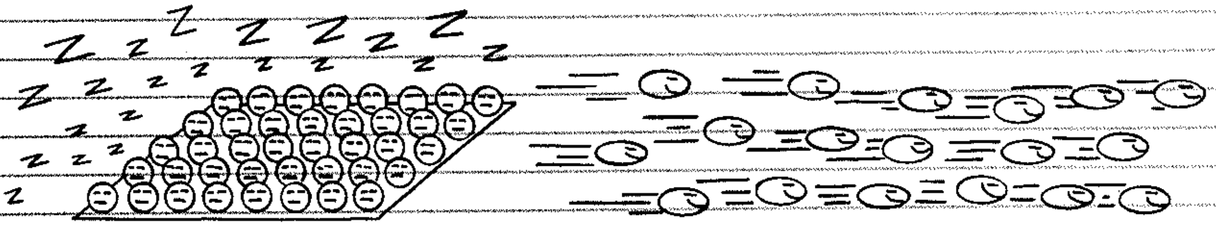
NEGATIVE ION



POSITIVE ION

☐ ELECTRONS — FREE ELECTRONS CAN MOVE AT HIGH SPEED THROUGH METALS, GASES AND A VACUUM. OR THEY CAN REST ON A SURFACE.

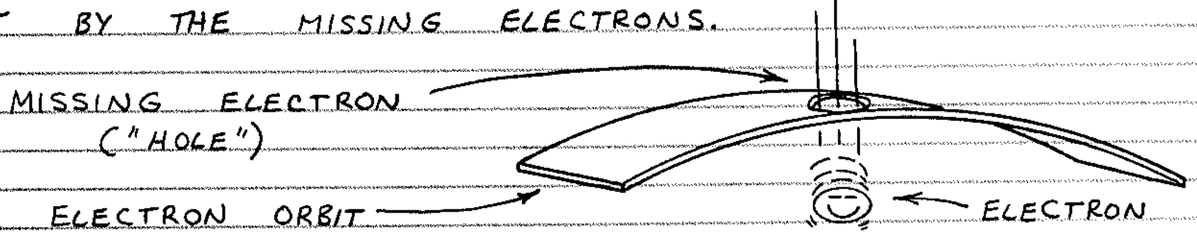
☐ MORE ABOUT FREE ELECTRONS — MANY TRILLIONS OF ELECTRONS CAN REST ON A SURFACE OR TRAVEL THROUGH SPACE OR MATTER AT NEAR THE SPEED OF LIGHT (186,000 MILES PER SECOND)!



RESTING ELECTRONS MOVING ELECTRONS

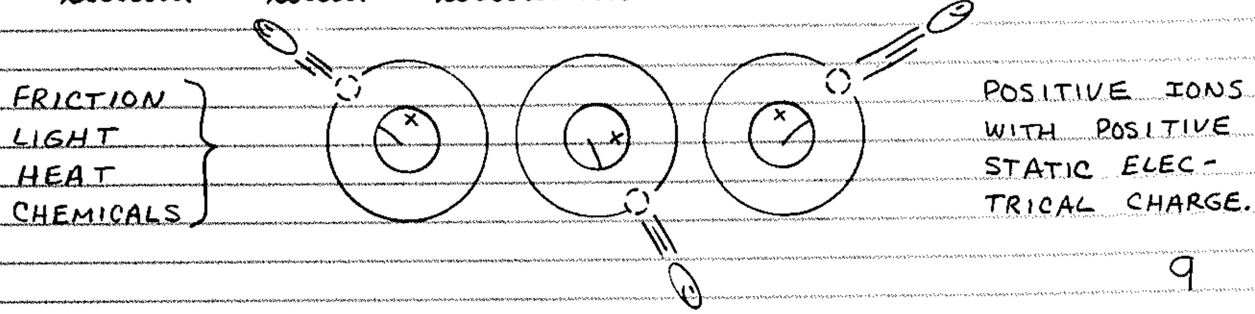
☐ RESTING ELECTRONS — A GROUP OF NEGATIVE ELECTRONS ON A SURFACE CAUSES THE SURFACE TO BE NEGATIVELY CHARGED. SINCE THE ELECTRONS ARE NOT MOVING, THE SURFACE CAN BE SAID TO HAVE A NEGATIVE STATIC ELECTRICAL CHARGE.

☐ MOVING ELECTRONS — A STREAM OF MOVING ELECTRONS IS CALLED AN ELECTRICAL CURRENT. RESTING ELECTRONS CAN QUICKLY FORM AN ELECTRICAL CURRENT IF PLACED NEAR A CLUSTER OF POSITIVE IONS. THE POSITIVELY CHARGED IONS WILL ATTRACT THE ELECTRONS WHICH WILL RUSH IN TO FILL THE "HOLES" OR VOIDS LEFT BY THE MISSING ELECTRONS.



MISSING ELECTRON ("HOLE")
ELECTRON ORBIT
ELECTRON

☐ MISSING ELECTRONS — MECHANICAL FRICTION, LIGHT, HEAT OR A CHEMICAL REACTION MAY REMOVE ELECTRONS FROM A SURFACE. THIS CAUSES THE SURFACE TO BE POSITIVELY CHARGED. SINCE THE POSITIVELY CHARGED ATOMS ARE AT REST, THE SURFACE CAN BE SAID TO HAVE A POSITIVE STATIC ELECTRICAL CHARGE.

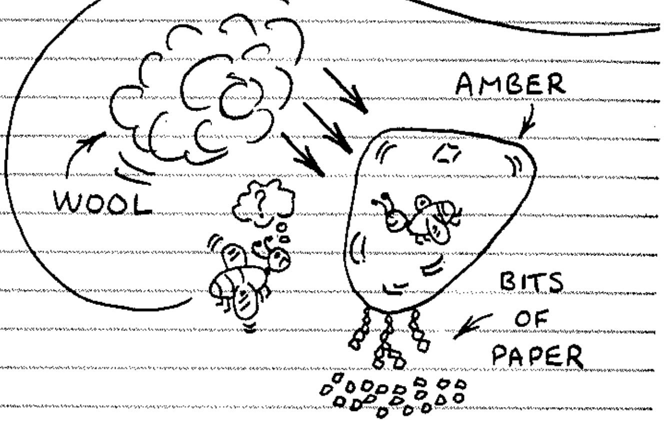


FRICTION
LIGHT
HEAT
CHEMICALS
POSITIVE IONS WITH POSITIVE STATIC ELECTRICAL CHARGE.

STATIC ELECTRICITY

YOU GENERATE STATIC ELECTRICITY EVERY TIME YOU WALK ACROSS A CARPET, PULL TAPE FROM A ROLL, REMOVE YOUR CLOTHING OR DRY CLOTHES IN A DRIER. MUCH OF THE TIME YOU DON'T EVEN REALIZE IT UNLESS THE AIR IS DRY AND THE STATIC CHARGE SUDDENLY CRACKLES, POPS AND FLASHES ITS WAY TO A NEW HOME. THESE STATIC CHARGES ARE CAUSED BY MECHANICAL FRICTION. BACK IN 600 B.C., THALES OF GREECE EXPERIMENTED WITH THE STATIC ELECTRICITY PRODUCED WHEN AMBER IS RUBBED WITH WOOL.

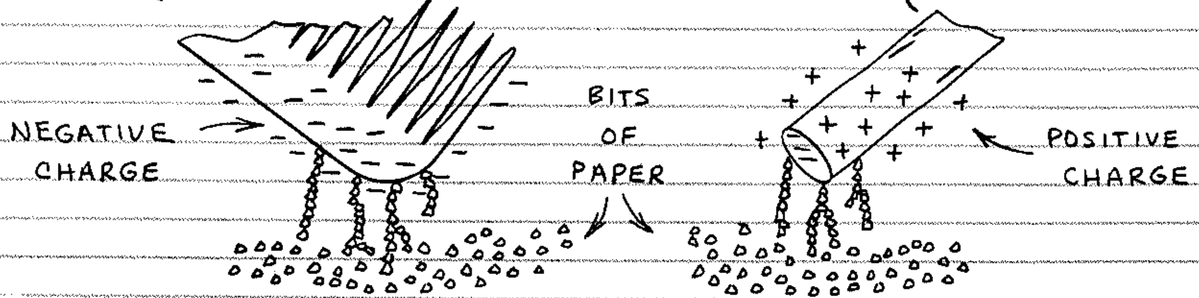
☐ AMBER — ONCE UPON A TIME SAP FLOWING FROM TREES HARDENED INTO CLEAR GOLDEN NODULES WHICH WERE EVENTUALLY BURIED IN THE EARTH. SOMETIMES, BEFORE IT HARDENED INTO AMBER, THE STICKY SAP ENTOMBED BITS OF PLANT MATTER, INSECTS AND EVEN DROPLETS OF WATER! A KIND OF NATURAL CASTING PLASTIC, AMBER IS EASILY ELECTRIFIED BY FRICTION. IT THEN ATTRACTS BITS OF PAPER.



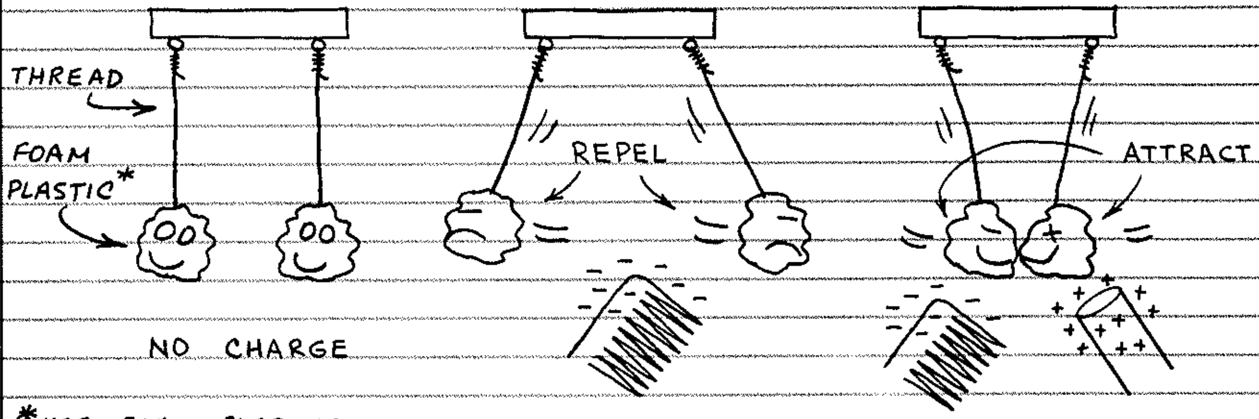
FAMOUS FACT: THE ELECTRON IS NAMED AFTER THE GREEK WORD FOR AMBER!

☐ ELECTRIFIED PLASTIC AND GLASS — RUN A PLASTIC COMB THROUGH YOUR HAIR ON A DRY DAY AND YOU'LL TRANSFER ELECTRONS FROM YOUR HAIR TO THE COMB. RUB A GLASS ROD WITH SILK OR THE SYNTHETIC FIBERS OF A PAINT BRUSH AND YOU'LL REMOVE ELECTRONS FROM THE GLASS. BOTH THE NEGATIVELY CHARGED COMB AND THE POSITIVELY CHARGED GLASS ROD WILL, LIKE AMBER, ATTRACT BITS OF PAPER. YOU CAN ELECTRIFY OR CHARGE MANY MATERIALS BY RUBBING THEM WITH FUR, WOOL, ETC. METAL? NO, THE CHARGE LEAKS AWAY.

COMB (AFTER STROKING HAIR) GLASS ROD (RUBBED WITH SILK)



☐ OPPOSITE AND LIKE CHARGES — HOW DO WE KNOW THE COMB AND GLASS ROD HAVE OPPOSITE CHARGES? A FUNDAMENTAL RULE OF ELECTRICITY IS LIKE CHARGES REPEL AND UNLIKE CHARGES ATTRACT. HERE'S AN EXPERIMENT THAT PROVES THE RULE AND ANSWERS THE QUESTION:

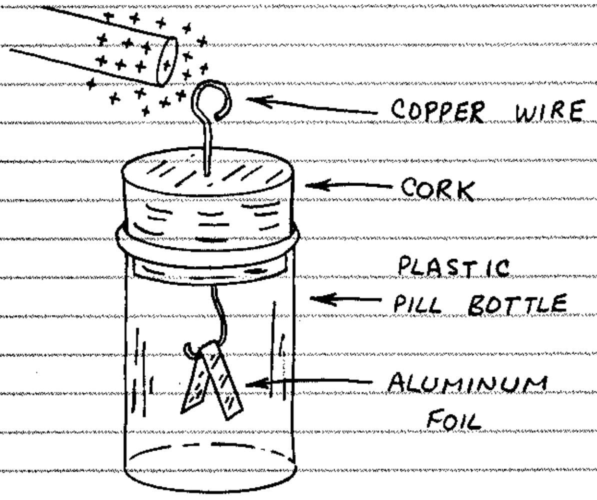


THREAD
FOAM PLASTIC*
NO CHARGE
REPEL
ATTRACT

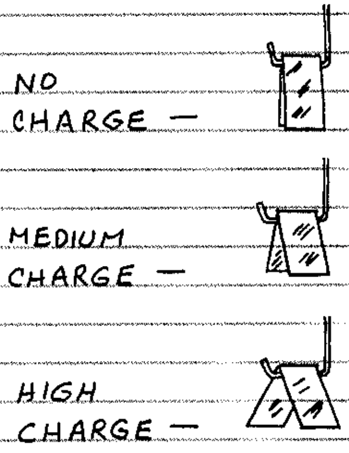
*USE FOAM PLASTIC PACKING MATERIAL.

REMEMBER: UNLIKE CHARGES ATTRACT — 
LIKE CHARGES REPEL —

☐ THE ELECTROSCOPE — THE FIRST INSTRUMENT DESIGNED TO DETECT AND MEASURE STATIC ELECTRICITY WAS THE ELECTROSCOPE. YOU CAN EASILY MAKE ONE.



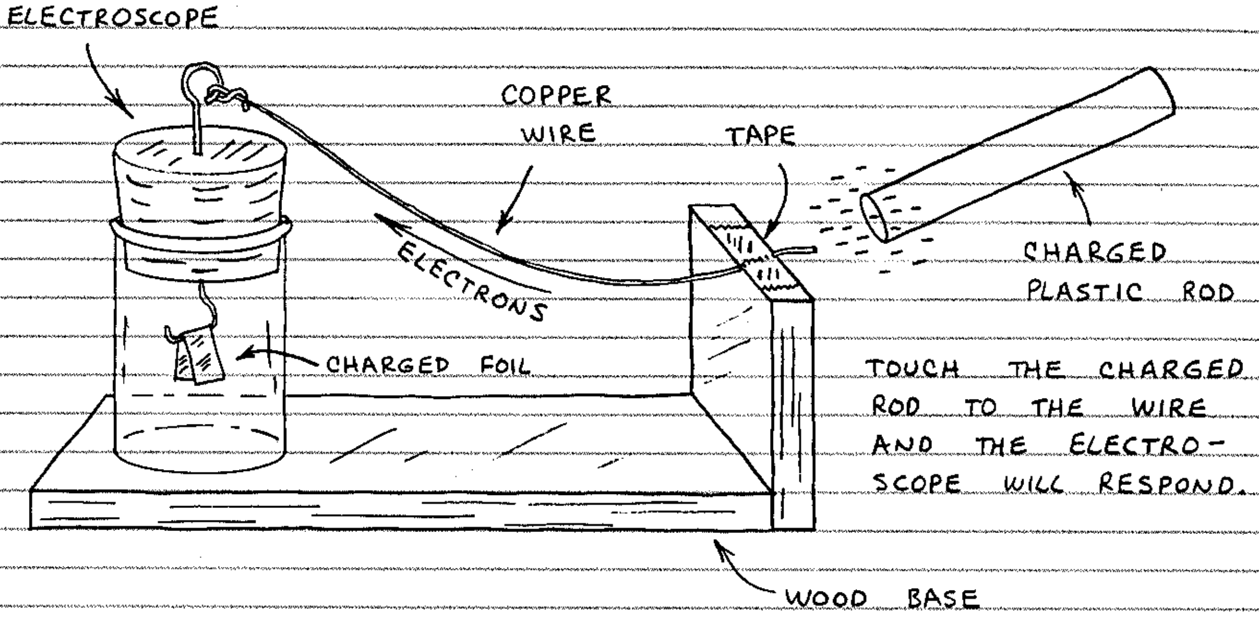
COPPER WIRE
CORK
PLASTIC PILL BOTTLE
ALUMINUM FOIL



NO CHARGE —
MEDIUM CHARGE —
HIGH CHARGE —

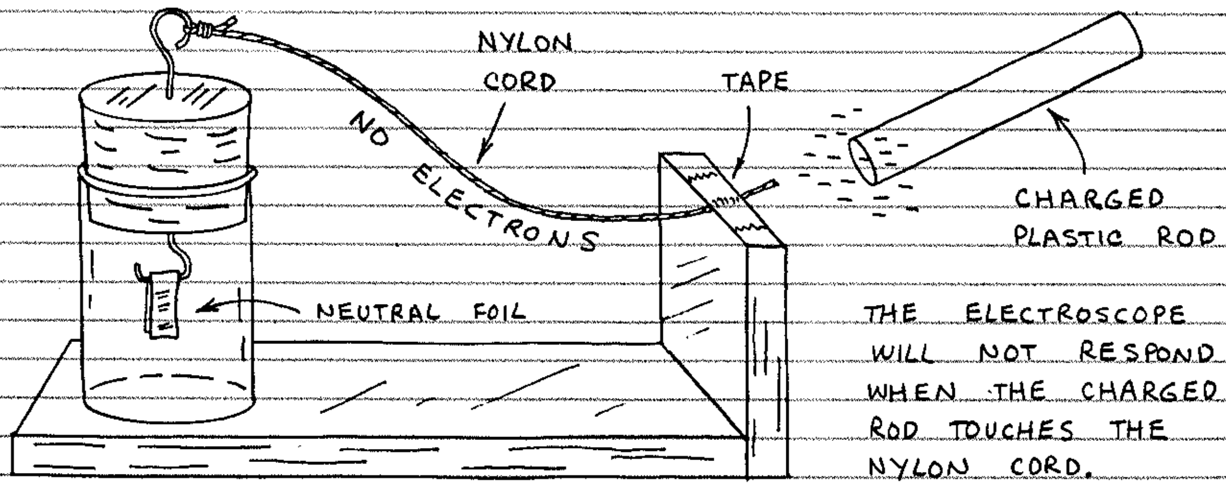
BE SURE THE FOLDED FOIL STRIP IS CLEAN AND DRY. WHEN YOU TOUCH A CHARGED OBJECT TO THE WIRE, THE TWO HALVES OF THE FOIL STRIP WILL BE GIVEN THE SAME CHARGE AND WILL THEREFORE FLY APART.

☐ CONDUCTORS AND INSULATORS— YOU CAN USE YOUR ELECTROSCOPE TO PROVE THAT ELECTRONS TRAVEL THROUGH SOME MATERIALS BUT NOT OTHERS. HINT: TRY THIS ON A DRY DAY! ELECTRONS CAN TRAVEL THROUGH MOIST AIR SO THE CHARGE ON YOUR ELECTROSCOPE WILL QUICKLY LEAK AWAY ON HUMID DAYS.



ELECTROSCOPE
COPPER WIRE
TAPE
ELECTRONS
CHARGED PLASTIC ROD
CHARGED FOIL
WOOD BASE

TOUCH THE CHARGED ROD TO THE WIRE AND THE ELECTROSCOPE WILL RESPOND.



NYLON CORD
TAPE
NO ELECTRONS
CHARGED PLASTIC ROD
NEUTRAL FOIL

THE ELECTROSCOPE WILL NOT RESPOND WHEN THE CHARGED ROD TOUCHES THE NYLON CORD.

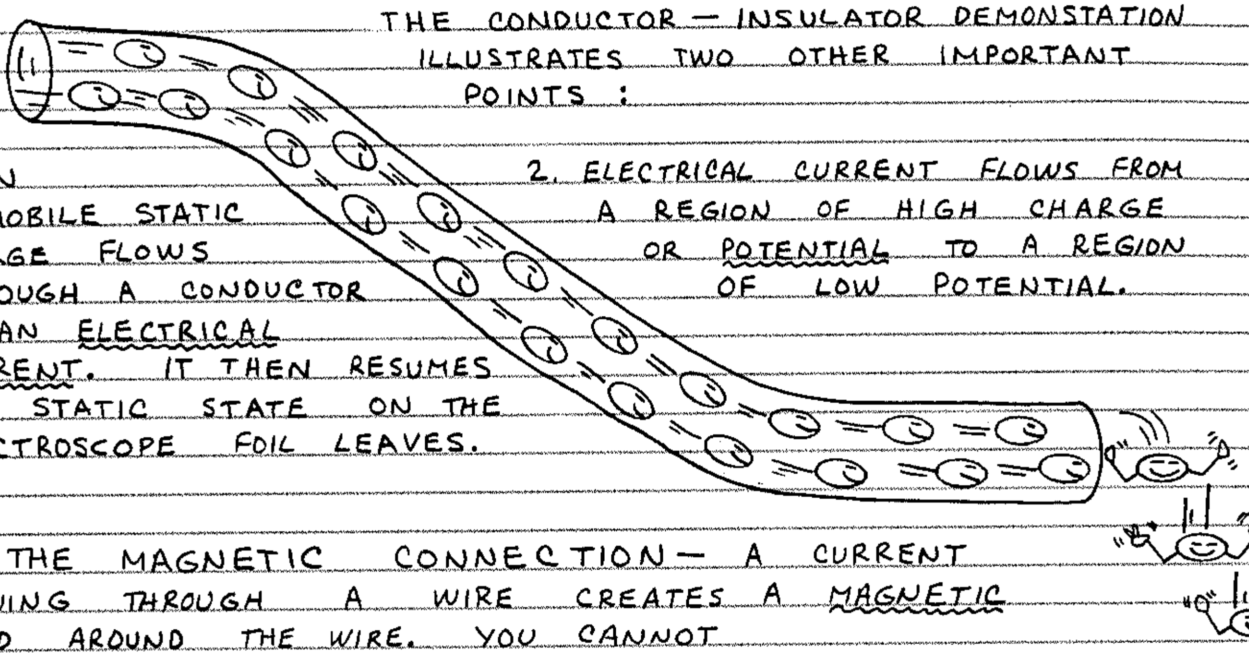
THIS DEMONSTRATION SHOWS THAT ELECTRONS CAN TRAVEL THROUGH SOME MATERIALS BUT NOT OTHERS. MATERIALS THROUGH WHICH ELECTRONS TRAVEL ARE CONDUCTORS. MATERIALS THROUGH WHICH ELECTRONS TRAVEL POORLY OR NOT AT ALL ARE INSULATORS.

CONDUCTORS INCLUDE SILVER, GOLD, IRON, COPPER, ETC.

INSULATORS INCLUDE GLASS, PLASTIC, RUBBER, WOOD, ETC.

ELECTRICAL CURRENT

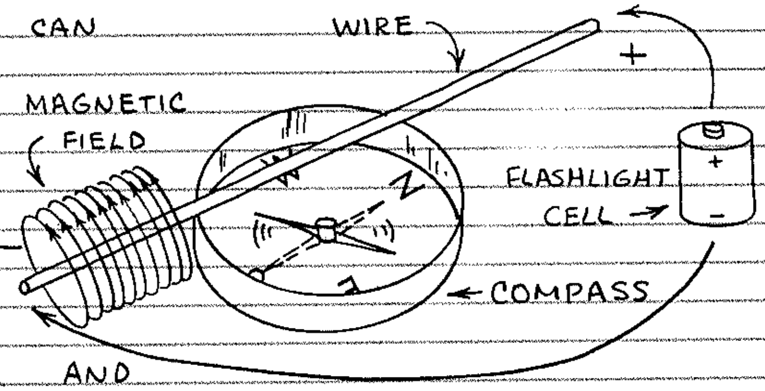
THE CONDUCTOR — INSULATOR DEMONSTATION ILLUSTRATES TWO OTHER IMPORTANT POINTS :



1. AN IMMOBILE STATIC CHARGE FLOWS THROUGH A CONDUCTOR AS AN ELECTRICAL CURRENT. IT THEN RESUMES ITS STATIC STATE ON THE ELECTROSCOPE FOIL LEAVES.

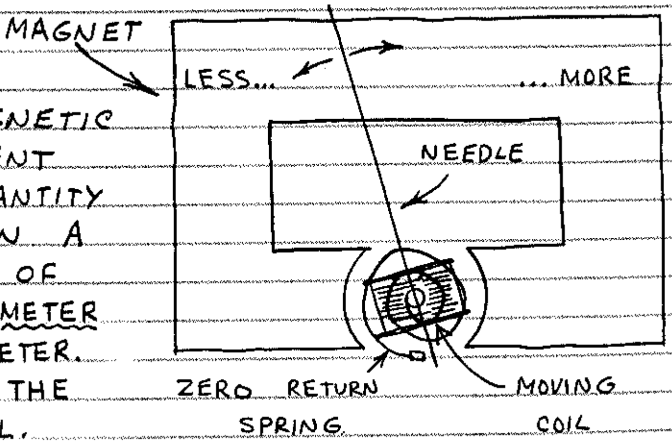
2. ELECTRICAL CURRENT FLOWS FROM A REGION OF HIGH CHARGE OR POTENTIAL TO A REGION OF LOW POTENTIAL.

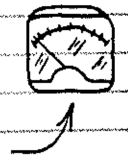
☐ THE MAGNETIC CONNECTION — A CURRENT FLOWING THROUGH A WIRE CREATES A MAGNETIC FIELD AROUND THE WIRE. YOU CANNOT SEE THE FIELD, BUT YOU CAN OBSERVE ITS EFFECT. ORIENT A COMPASS SO ITS NEEDLE POINTS TO THE NORTH (N) MARK. PLACE A COPPER WIRE OVER AND PARALLEL TO THE NEEDLE. THEN CONNECT A FLASHLIGHT CELL ACROSS THE WIRE AND THE NEEDLE WILL MOVE AWAY FROM ITS NORTH-SOUTH ORIENTATION. (LEAVE THE WIRE CONNECTED FOR ONLY AN INSTANT TO PREVENT THE CELL FROM OVERHEATING!)



☐ MEASURING CURRENT ELECTRICITY —

THE PHYSICAL (OR MECHANICAL) MOTION OF A MAGNETIC COMPASS NEEDLE IN A MAGNETIC FIELD PROVIDES A CONVENIENT WAY TO MEASURE THE QUANTITY OF CURRENT FLOWING IN A WIRE. THIS IS THE BASIS OF THE MOVING COIL CURRENT METER USED IN THE ANALOG MULTIMETER. TO PROVIDE HIGH SENSITIVITY, THE WIRE IS WRAPPED AS A COIL.





P. 26

DIRECT CURRENT ELECTRICITY

AN ELECTRICAL CURRENT CAN FLOW IN EITHER OF TWO DIRECTIONS THROUGH A CONDUCTOR. IF IT FLOWS IN ONLY ONE DIRECTION, WHETHER STEADILY OR IN PULSES, IT'S CALLED *DIRECT CURRENT* (DC). IT'S IMPORTANT TO BE ABLE TO SPECIFY THE QUANTITY AND POWER OF A DIRECT CURRENT. HERE ARE THE KEY TERMS:

☐ CURRENT (I) — CURRENT IS THE QUANTITY OF ELECTRONS PASSING A GIVEN POINT. THE UNIT OF CURRENT IS THE *AMPERE*. ONE AMPERE IS 6,280,000,000,000,000,000 (6.28×10^{18}) ELECTRONS PASSING A POINT IN ONE SECOND.

☐ VOLTAGE (V OR E) — VOLTAGE IS ELECTRICAL PRESSURE OR FORCE. VOLTAGE IS SOMETIMES REFERRED TO AS *POTENTIAL*. *VOLTAGE DROP* IS THE DIFFERENCE IN VOLTAGE BETWEEN THE TWO ENDS OF A CONDUCTOR THROUGH WHICH CURRENT IS FLOWING. IF WE COMPARE CURRENT TO WATER FLOWING THROUGH A PIPE, THEN VOLTAGE IS THE WATER PRESSURE.

☐ POWER (P) — THE WORK PERFORMED BY AN ELECTRICAL CURRENT IS CALLED POWER. THE UNIT OF POWER IS THE *WATT*. THE POWER OF A DIRECT CURRENT IS ITS VOLTAGE TIMES ITS CURRENT.

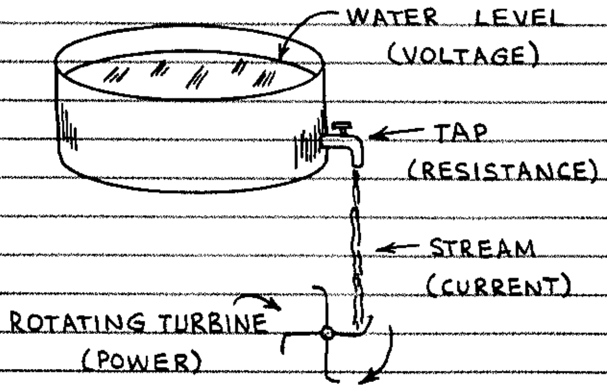
☐ RESISTANCE (R) — CONDUCTORS ARE NOT PERFECT. THEY RESIST TO SOME DEGREE THE FLOW OF CURRENT. THE UNIT OF RESISTANCE IS THE *OHM* (Ω). A POTENTIAL DIFFERENCE OF ONE VOLT WILL FORCE A CURRENT OF ONE AMPERE THROUGH A RESISTANCE OF ONE OHM. THE RESISTANCE OF A CONDUCTOR IS ITS VOLTAGE DROP DIVIDED BY THE CURRENT FLOWING THROUGH THE CONDUCTOR.

☐ MR. OHM'S LAW — GIVEN ANY TWO OF THE ABOVE, YOU CAN FIND THE OTHER TWO USING THESE FORMULAS KNOWN AS *OHM'S LAW*:

$$V = I \times R$$
$$I = V / R$$
$$R = V / I$$
$$P = V \times I \text{ (OR) } I^2 \times R$$

WE'LL REFER TO OHM'S LAW LATER IN THIS BOOK...

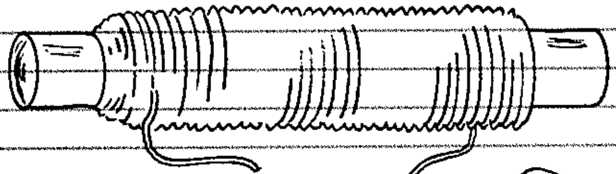
☐ SUMMING UP — THIS IS THE "WATER ANALOGY":



USING DIRECT CURRENT

THERE ARE SO MANY USES FOR DIRECT CURRENT ELECTRICITY NO SINGLE BOOK CAN DESCRIBE THEM ALL. HERE'S A PAGE OF SEVERAL DESIGNED AROUND A SINGLE WIRE COIL YOU CAN EASILY MAKE FROM A 1-½ TO 3-INCH SECTION OF A SODA STRAW AND AT LEAST 30-FEET OF 30 GAUGE, LACQUER COATED WIRE. SECURE THE COIL IN PLACE WITH TAPE. REMOVE INSULATION FROM ENDS OF COIL WITH FINE SAND PAPER.

(TWICE ACTUAL SIZE)



☐ ELECTROMAGNET — INSERT A STEEL NAIL IN THE COIL, CONNECT THE LEADS TO A 9-VOLT BATTERY, AND THE NAIL WILL BECOME A MAGNET UNTIL THE POWER IS DISCONNECTED. (IT MAY RETAIN SOME MAGNETISM.)

☐ SOLENOID — THIS IS A "SUCKING MAGNET." APPLY POWER TO COIL AND NAIL WILL BE PULLED RAPIDLY INSIDE.

ASSIGNMENT

EXPLAIN IN 25 WORDS OR LESS HOW THIS THING ACTUALLY WORKS...

MAKING DIRECT CURRENT ELECTRICITY

A SURPRISING NUMBER OF WAYS EXIST FOR PRODUCING DIRECT CURRENT. HERE ARE THE BIGGIES:

☐ CHEMICAL GENERATORS — ELECTROLYTES ARE CHEMICAL SOLUTIONS THAT CONTAIN MANY IONS. FOR EXAMPLE, DISSOLVE TABLE SALT IN WATER AND THE SALT WILL BREAK DOWN INTO POSITIVE SODIUM IONS AND NEGATIVE CHLORINE IONS. IF TWO DISSIMILAR METAL PLATES ARE IMMERSED IN THE SALT SOLUTION, THE POSITIVE IONS WILL MIGRATE TOWARD ONE PLATE AND THE NEGATIVE IONS WILL MIGRATE TOWARD THE OTHER. IF THE TWO PLATES ARE CONNECTED TOGETHER BY A CONDUCTOR, A CURRENT WILL FLOW THROUGH THE SOLUTION (AS IONS) AND THE CONDUCTOR (AS ELECTRONS). THIS KIND OF GENERATOR IS CALLED A WET CELL. CELLS IN WHICH THE ELECTROLYTE IS ABSORBED BY PAPER OR FORMED INTO A PASTE ARE CALLED DRY CELLS. HERE ARE SOME CHEMICAL GENERATORS YOU CAN MAKE. HAVE FUN!

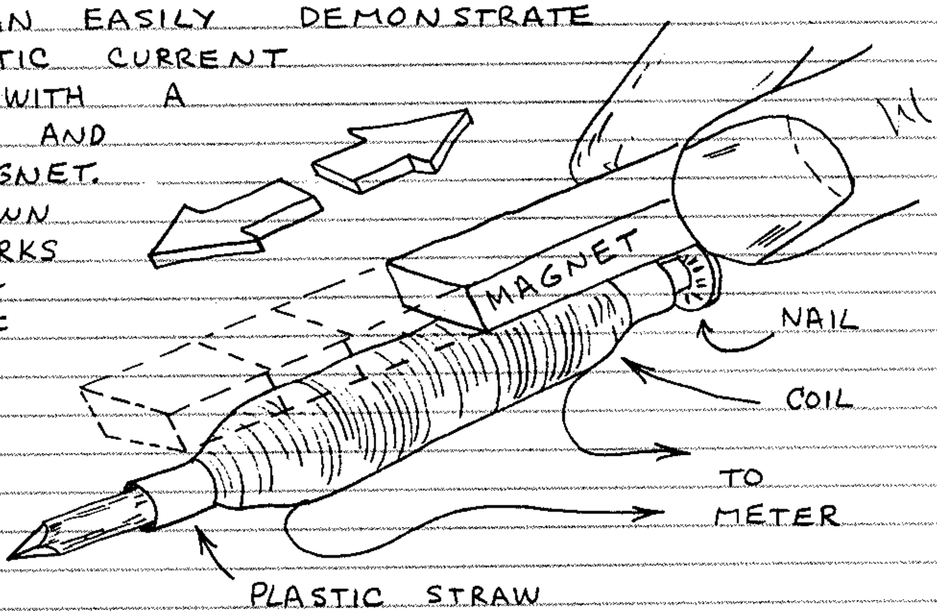
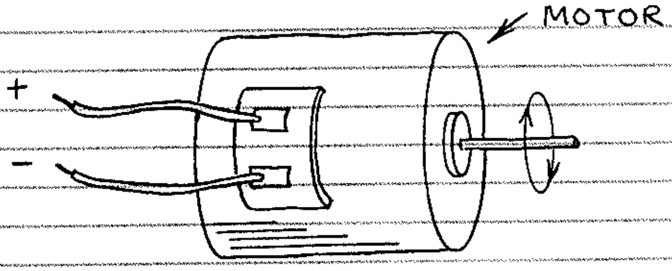
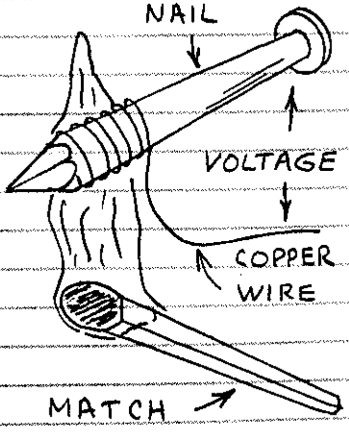
☐ ELECTROMAGNETIC GENERATORS— A CURRENT FLOWING THROUGH A CONDUCTOR ESTABLISHES A MAGNETIC FIELD AROUND THE CONDUCTOR. THIS EFFECT WORKS BOTH WAYS SO THAT A CURRENT WILL FLOW IN A CONDUCTOR WHICH IS MOVED THROUGH A MAGNETIC FIELD. YOU CAN EASILY DEMONSTRATE ELECTROMAGNETIC CURRENT GENERATION WITH A COIL OF WIRE AND A SMALL MAGNET. (THE COIL SHOWN ON PAGE 15 WORKS FINE.) CONNECT THE LEADS OF THE COIL TO A METER DESIGNED TO SENSE MICROAMPERES. INSERT A STEEL NAIL THROUGH THE COIL AND STROKE THE MAGNET BACK AND FORTH ACROSS THE COIL. THE METER WILL INDICATE A FEW MICROAMPERES EACH STROKE. THE POLARITY (DIRECTION) OF THE CURRENT WILL REVERSE ON THE BACK STROKES. WANT A READY-MADE GENERATOR? JUST ROTATE THE SHAFT OF A SMALL DC MOTOR. MOST SUCH MOTORS WILL PRODUCE A POTENTIAL DIFFERENCE OF UP TO SEVERAL VOLTS! YOU CAN ADD A PROPELLER TO MAKE A WIND POWERED GENERATOR.



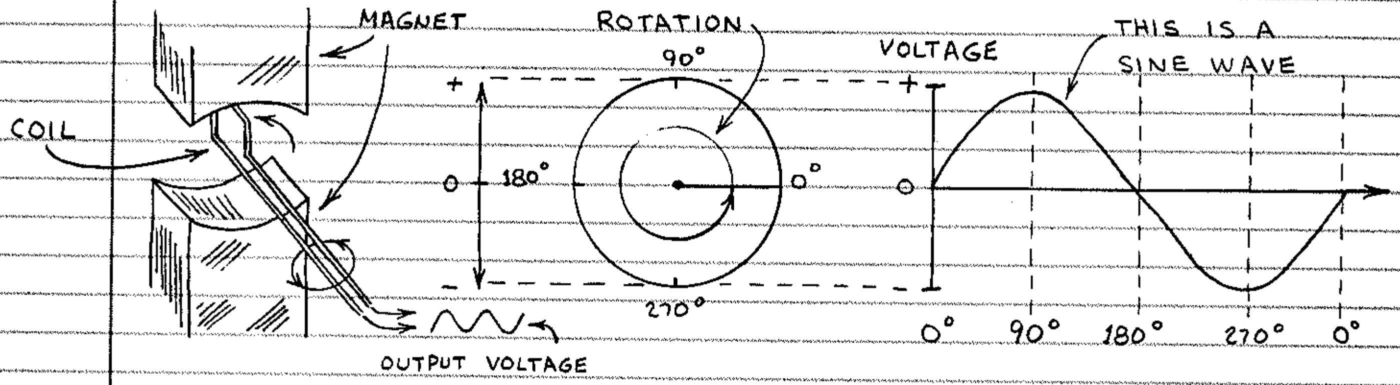


☐ THERMOELECTRIC GENERATORS— IF A JUNCTION OF TWO DISSIMILAR METALS IS HEATED, A CURRENT WILL BE PRODUCED. COPPER WIRE WRAPPED AROUND THE END OF A STEEL NAIL WILL GENERATE A FEW THOUSANDTHS OF A VOLT WHEN HEATED BY THE FLAME OF A MATCH. JUNCTIONS LIKE IRON AND CONSTANTAN PRODUCE MUCH HIGHER VOLTAGES. (THIS IS THE SEEBECK EFFECT.)



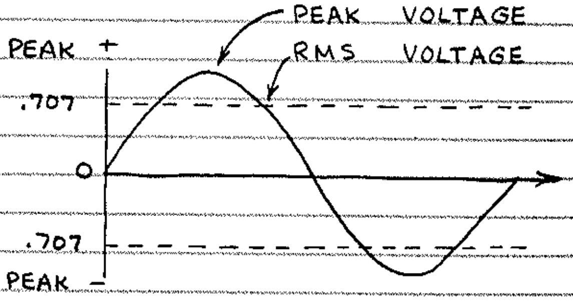
ALTERNATING CURRENT ELECTRICITY

LOOK BACK AT THE HOMEMADE COIL AND MAGNET "GENERATOR" ON THE PRECEEDING PAGE. WHEN THE MAGNET IS STROKED IN ONE DIRECTION ALONG THE COIL, ELECTRONS IN THE WIRE ARE MOVED IN ONE DIRECTION AND A DIRECT CURRENT IS PRODUCED. ON THE BACK STROKE, UNLESS THE MAGNET IS MOVED AWAY FROM THE COIL, THE DIRECTION OF CURRENT FLOW IS REVERSED. THEREFORE, IF THE MAGNET IS STROKED BACK AND FORTH ALONG THE COIL, A CURRENT WHICH ALTERNATES IN DIRECTION OR POLARITY IS PRODUCED. IT'S CALLED AN ALTERNATING CURRENT. ALTERNATING CURRENT (AC) IS USUALLY PRODUCED BY ROTATING A COIL IN A MAGNETIC FIELD.



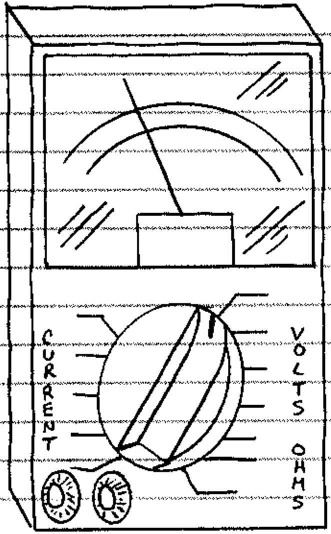
ROTATING COIL VOLTAGE OUTPUT AC SINE WAVE

☐ SINE WAVE MEASUREMENT — AC VOLTAGE IS USUALLY SPECIFIED AT A VALUE EQUAL TO THE DC VOLTAGE CAPABLE OF DOING THE SAME WORK. FOR A SINE WAVE THIS VALUE IS 0.707 TIMES THE PEAK VOLTAGE. IT'S CALLED THE RMS (ROOT-MEAN-SQUARE) VOLTAGE. THE PEAK VOLTAGE (OR CURRENT) IS 1.41 TIMES THE RMS VALUE. HOUSEHOLD LINE VOLTAGE IS SPECIFIED ACCORDING TO ITS RMS VALUE. THEREFORE, A HOUSEHOLD VOLTAGE OF 120-VOLTS CORRESPONDS TO A PEAK VOLTAGE OF 120 × 1.41 OR 169.2-VOLTS.

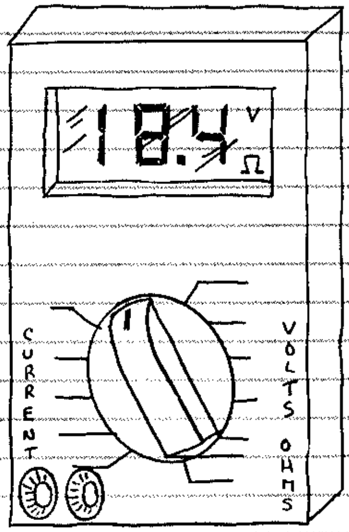


☐ WHY AC IS USED — AC IS BETTER SUITED THAN DC FOR TRANSMISSION THROUGH LONG DISTANCE POWER LINES. A WIRE CARRYING AC WILL INDUCE A CURRENT IN A NEARBY WIRE. THIS IS THE PRINCIPLE BEHIND THE TRANSFORMER.

MEASURING AC AND DC



YOU CAN EASILY MEASURE AC AND DC VOLTAGE AND CURRENT WITH AN INSTRUMENT CALLED THE MULTIMETER. ANALOG MULTIMETERS USE A MOVING COIL METER. DIGITAL MULTIMETERS HAVE A DIGITAL READOUT. THE MULTIMETER IS THE SINGLE MOST IMPORTANT ELECTRONIC TEST INSTRUMENT.



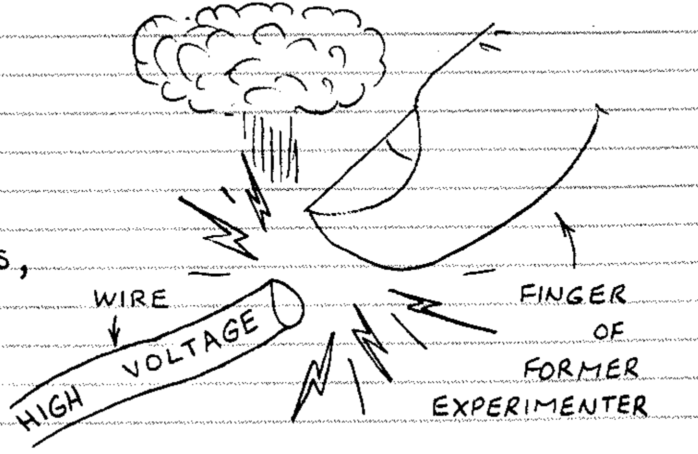
☐ ANALOG MULTIMETER — LESS EXPENSIVE, SOMEWHAT LESS PRECISE THAN DIGITAL TYPES. BEST BY FAR FOR OBSERVING THE TREND OF A SLOWLY CHANGING VOLTAGE, CURRENT OR RESISTANCE.

☐ DIGITAL MULTIMETER — HIGHLY ACCURATE AND EASIER TO READ THAN ANALOG TYPES. BEST FOR FINDING THE PRECISE VALUE OF A VOLTAGE, CURRENT OR RESISTANCE.

☐ SUMMING UP MULTIMETERS — THEY'RE INDISPENSABLE! EVEN IF YOU HAVE ONLY A PASSING INTEREST YOU SHOULD CONSIDER BUYING ONE BECAUSE IT HAS MANY USES IN THE HOME, ON THE JOB AND WHEN WORKING WITH APPLIANCES AND MOTOR VEHICLES. IF YOU'RE SERIOUS ABOUT ELECTRONICS, CONSIDER BUYING A QUALITY HIGH-IMPEDANCE MULTIMETER THAT WILL HAVE LITTLE OR NO EFFECT ON THE DEVICE OR CIRCUIT YOU'RE MEASURING. IDEALLY, YOU SHOULD HAVE BOTH THE ANALOG AND DIGITAL TYPES.

ELECTRICAL SAFETY

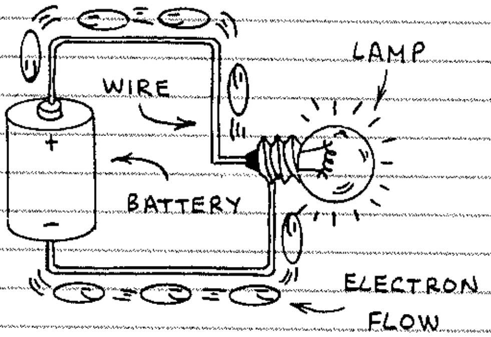
ELECTRICITY CAN KILL! IF YOU WANT TO BE AROUND LONG ENOUGH TO ENJOY EXPERIMENTING WITH ELECTRONICS, ALWAYS TREAT ELECTRICITY WITH THE RESPECT IT DESERVES. WE'LL LOOK AT SAFETY AGAIN LATER.



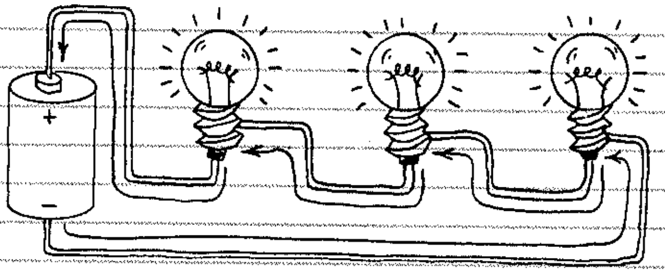
ELECTRICAL CIRCUITS

AN ELECTRICAL CIRCUIT IS ANY ARRANGEMENT THAT PERMITS AN ELECTRICAL CURRENT TO FLOW. A CIRCUIT CAN BE AS SIMPLE AS A BATTERY CONNECTED TO A LAMP OR AS COMPLICATED AS A DIGITAL COMPUTER.

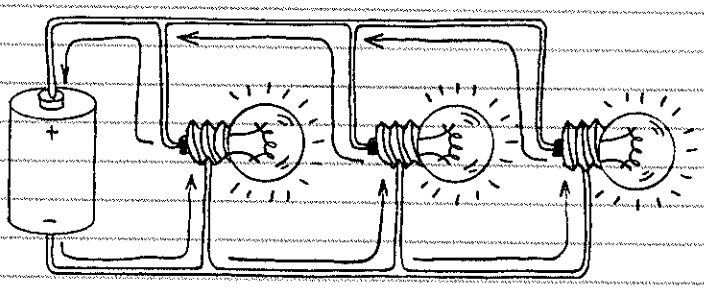
☐ A BASIC CIRCUIT — THIS BASIC CIRCUIT CONSISTS OF A SOURCE OF ELECTRICAL CURRENT (A BATTERY), A LAMP AND TWO CONNECTION WIRES. THE PART OF A CIRCUIT WHICH PERFORMS WORK IS CALLED THE LOAD. HERE THE LOAD IS THE LAMP. IN OTHER CIRCUITS THE LOAD CAN BE A MOTOR, A HEATING ELEMENT, AN ELECTROMAGNET, ETC.



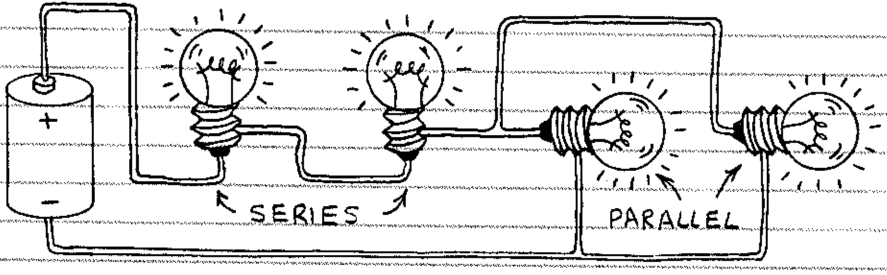
☐ A SERIES CIRCUIT — A CIRCUIT MAY INCLUDE MORE THAN ONE COMPONENT (SWITCH, LAMP, MOTOR, ETC.). A SERIES CIRCUIT IS FORMED WHEN CURRENT FLOWING THROUGH ONE COMPONENT FIRST FLOWS THROUGH ANOTHER. (ARROWS SHOW DIRECTION OF ELECTRON FLOW.)



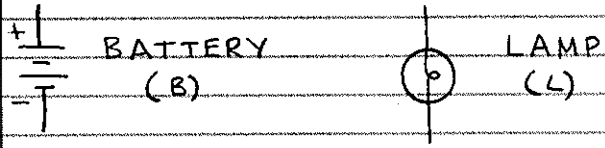
☐ A PARALLEL CIRCUIT — A PARALLEL CIRCUIT IS FORMED WHEN TWO OR MORE COMPONENTS ARE CONNECTED SO CURRENT CAN FLOW THROUGH ONE COMPONENT WITHOUT HAVING FIRST TO FLOW THROUGH ANOTHER.



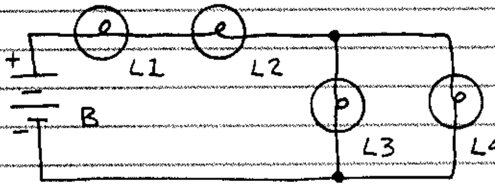
☐ A SERIES-PARALLEL CIRCUIT — MANY ELECTRICAL CIRCUITS ARE BOTH SERIES AND PARALLEL. ALL PROVIDE A COMPLETE PATH BETWEEN THE CIRCUIT AND ITS POWER SUPPLY.



☐ CIRCUIT DIAGRAMS— THUS FAR THE ELECTRICAL CIRCUITS SHOWN IN THIS BOOK HAVE BEEN ILLUSTRATED IN PICTORIAL FORM. PICTORIAL VERSIONS OF CIRCUITS WILL BE USED IN THE NEXT SEVERAL CHAPTERS AS WELL. LATER IN THE BOOK THE PICTORIALS WILL BE REPLACED BY CIRCUIT DIAGRAMS. IN A CIRCUIT DIAGRAM PICTORIAL VIEWS OF COMPONENTS ARE REPLACED BY COMPONENT SYMBOLS.



COMPONENT SYMBOLS

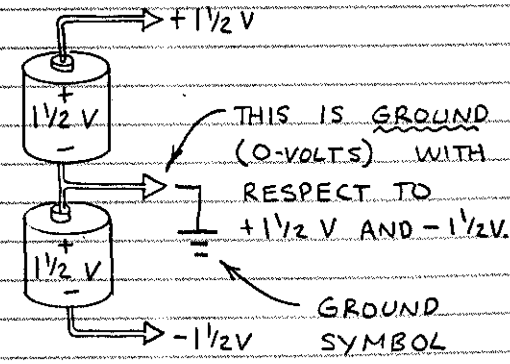


SERIES—PARALLEL CIRCUIT

☐ ELECTRICAL "SHORT" CIRCUIT— WHEN A WIRE OR OTHER CONDUCTOR IS PLACED ACROSS THE CONNECTIONS OF A COMPONENT, SOME OR ALL OF ANY CURRENT IN THE CIRCUIT MAY TAKE A SHORTCUT THROUGH THE CONDUCTOR. "SHORT" CIRCUITS SUCH AS THIS ARE USUALLY UNDESIRABLE AT BEST. THEY CAN CAUSE BATTERIES TO RAPIDLY LOSE THEIR CAPACITY. AND THEY CAN CAUSE DAMAGE TO WIRING AND COMPONENTS. "SHORT" CIRCUITS CAN EVEN CAUSE ENOUGH HEAT TO IGNITE THE INSULATION ON A WIRE! CAUTION: THE HUMAN BODY CONDUCTS ELECTRICITY. THEREFORE CARELESSLY TOUCHING AN ELECTRICAL CIRCUIT MAY CAUSE A "SHORT" CIRCUIT. IF THE VOLTAGE AND CURRENT ARE HIGH ENOUGH, YOU MAY RECEIVE A DANGEROUS OR EVEN LETHAL SHOCK.

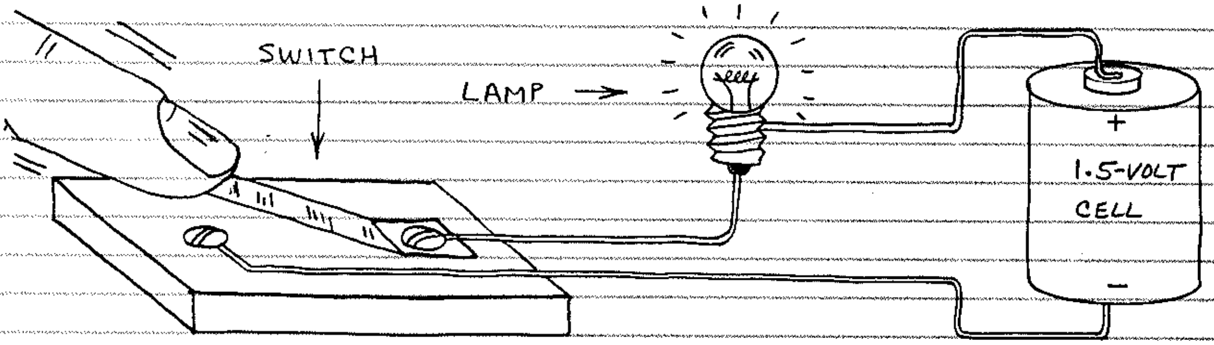
☐ ELECTRICAL "GROUND"— ONE OF THE WIRES OF THE AC LINE IS CONNECTED TO EARTH BY A METAL ROD. METAL ENCLOSURES OF ELECTRICALLY POWERED DEVICES ARE CONNECTED TO THIS GROUND WIRE. THIS PREVENTS A SHOCK HAZARD SHOULD A NON-GROUNDED WIRE MAKE CONTACT WITH THE METAL ENCLOSURE. WITHOUT THE GROUND CONNECTION, A PERSON TOUCHING THE DEVICE WHILE STANDING ON THE GROUND OR A WET FLOOR MIGHT RECEIVE A DANGEROUS SHOCK.

GROUND ALSO REFERS TO THE POINT IN A CIRCUIT AT ZERO VOLTAGE, WHETHER OR NOT IT'S CONNECTED TO GROUND. FOR INSTANCE, THE MINUS (-) SIDE OF THE BATTERY IN THE CIRCUITS ABOVE AND ON THE PRECEEDING PAGE CAN BE CONSIDERED GROUND.

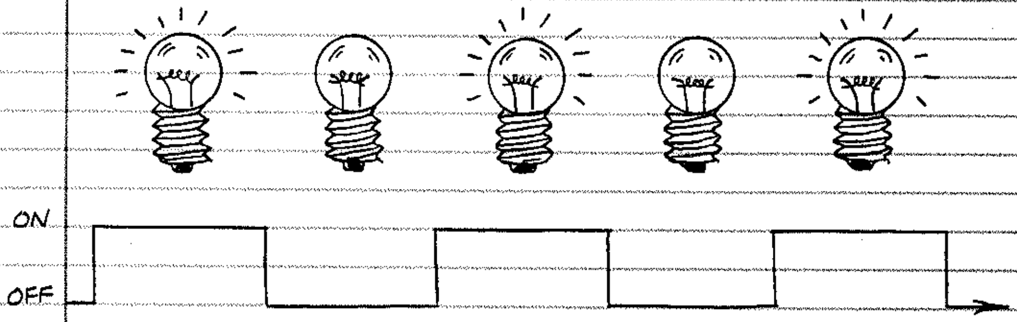


PULSES, WAVES, SIGNALS AND NOISE

ELECTRONICS IS THE STUDY AND APPLICATION OF ELECTRONS, THEIR BEHAVIOUR AND THEIR EFFECTS. THE SIMPLEST APPLICATIONS FOR ELECTRONS ARE STRAIGHTFORWARD AC AND DC CIRCUITS IN WHICH A CURRENT IS USED TO POWER LAMPS, ELECTROMAGNETS, MOTORS, SOLENOIDS AND SIMILAR DEVICES. WHAT TAKES ELECTRONICS FAR BEYOND THESE BASIC APPLICATIONS IS THE EASE WITH WHICH STREAMS OF ELECTRONS CAN BE CONTROLLED AND MANIPULATED.

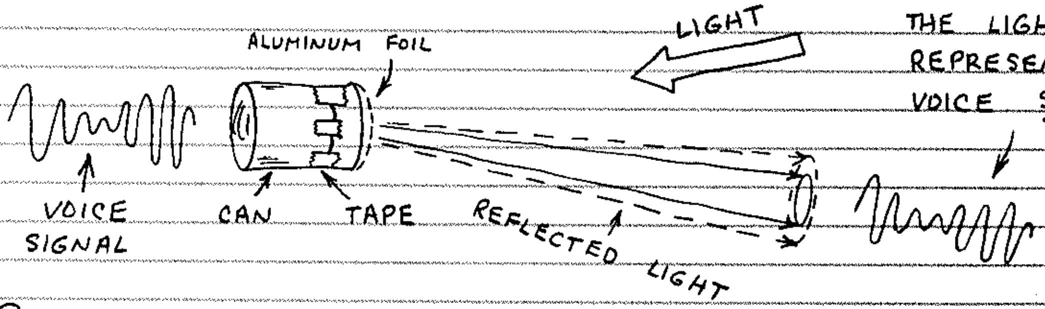


THIS SIMPLE CIRCUIT IS REALLY MORE USEFUL THAN IT FIRST APPEARS BECAUSE IT CAN SEND INFORMATION BY CONVERTING A PLANNED SEQUENCE OF SWITCH CLOSURES INTO FLASHES OF LIGHT.



THE FLASHES OF THE LAMP CAN BE REPRESENTED BY A DIAGRAM LIKE THIS...

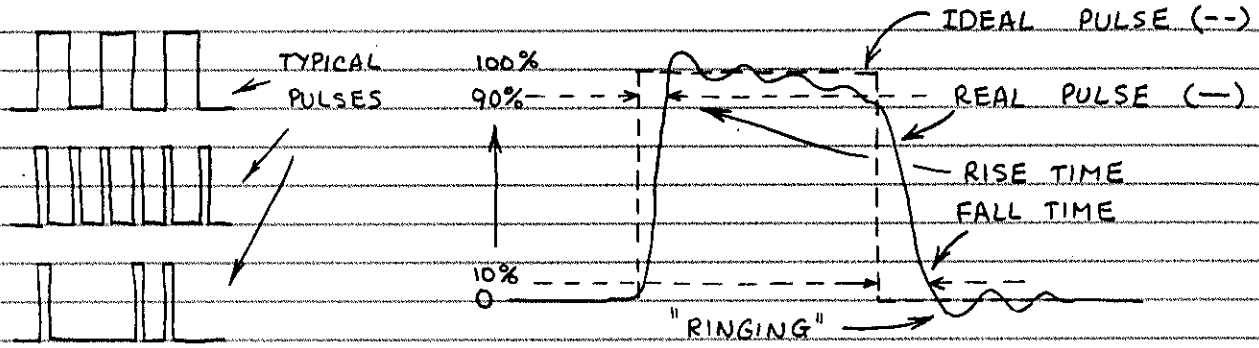
PATTERNS OF FLASHES OR PULSES LIKE THESE CAN REPRESENT COMPLEX INFORMATION LIKE SPEECH. OR SPEECH CAN BE TRANSFORMED INTO PROPORTIONAL VARIATIONS IN THE BRIGHTNESS OF A LAMP. HERE'S A SIMPLE WAY TO SEND VOICE OVER A BEAM OF REFLECTED LIGHT:



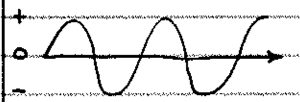
THE LIGHT INTENSITY REPRESENTS THE VOICE SIGNAL.

P. 123

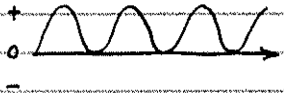
☐ PULSES — A PULSE IS A SUDDEN, BRIEF INCREASE OR DECREASE IN A CURRENT FLOW. THE IDEAL PULSE WOULD HAVE AN INSTANTANEOUS RISE AND FALL, BUT REAL PULSES ARE NOT SO IDEAL.



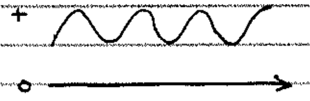
☐ WAVES — A WAVE IS A PERIODIC FLUCTUATION IN A CURRENT OR VOLTAGE. WAVES MAY HAVE A SINGLE POLARITY (DC) OR BOTH POSITIVE AND NEGATIVE COMPONENTS (AC). THERE ARE MANY KINDS OF WAVES. HERE ARE A FEW:



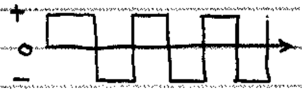
AC SINE WAVE



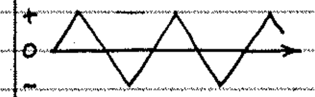
DC SINE WAVE



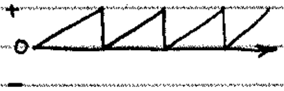
DC+ SINE WAVE



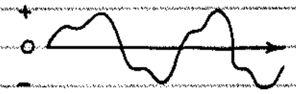
AC SQUARE WAVE



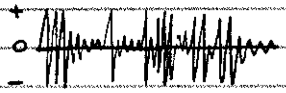
AC TRIANGLE WAVE



DC RAMP



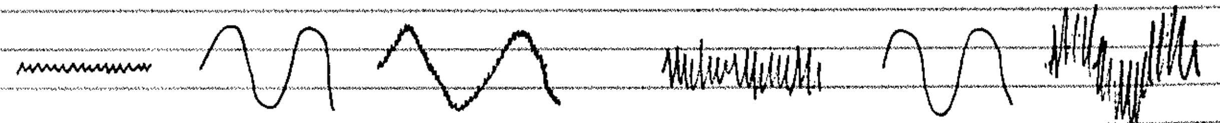
COMPLEX SINE WAVE



VOICE

☐ SIGNALS — A SIGNAL IS A PERIODIC WAVEFORM THAT CONVEYS INFORMATION. THE PROCESS THAT GENERATES THE WAVEFORM IS CALLED MODULATION. SIGNALS CAN BE AC, DC OR AC RIDING ON A DC LEVEL. THEIR ENEMY IS...

☐ NOISE — ALL ELECTRONIC DEVICES AND CIRCUITS GENERATE SMALL, RANDOM ELECTRICAL CURRENTS. WHEN THESE CURRENTS ARE UNWANTED, THEY'RE CALLED NOISE. NOISE CAN ALSO ENTER ELECTRONIC CIRCUITS BY MEANS OF THE ELECTROMAGNETIC WAVES GENERATED BY LIGHTNING, AUTOMOBILE IGNITION SYSTEMS, ELECTRIC MOTORS AND POWER LINES. WHILE NOISE MAY HAVE A LEVEL OF ONLY A FEW MILLIONTHS OF A VOLT OR AMPERE, IT MAY EASILY OBSCURE AN EQUALLY LOW LEVEL SIGNAL.



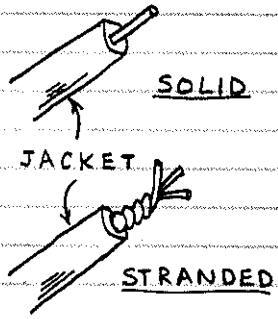
NOISE + SIGNAL = NOISY SIGNAL   NOISE + SIGNAL = ???

2. ELECTRONIC COMPONENTS

DOZENS OF DIFFERENT FAMILIES OF PARTS AND COMPONENTS BLOCK, CARRY, CONTROL, SELECT, STEER, SWITCH, STORE, MANIPULATE, REPLICATE, MODULATE AND EXPLOIT AN ELECTRICAL CURRENT. THOSE THAT USE SEMICONDUCTING CRYSTALS ARE SO IMPORTANT WE'LL DEVOTE AN ENTIRE CHAPTER TO THEM. YOU'LL FIND JUST ABOUT ALL THE REMAINING PARTS YOU SHOULD KNOW ABOUT IN THIS CHAPTER.

WIRE AND CABLE

USED TO CARRY AN ELECTRICAL CURRENT. MOST WIRE IS MADE FROM A LOW RESISTANCE METAL LIKE COPPER. SOLID WIRE IS A SINGLE CONDUCTOR. STRANDED WIRE IS TWO OR MORE TWISTED OR BRAIDED BARE CONDUCTORS. MOST WIRE IS PROTECTED BY AN INSULATING COVERING OF PLASTIC, RUBBER OR LACQUER. WIRE WHICH HAS BEEN TINNED IS EASIER TO SOLDER.



SPECIFICATIONS FOR BARE COPPER WIRE

GAUGE	DIAMETER (INCHES)	FEET/POUND	FEET/OHM
16	.05082	127.9	249.00
18	.04030	203.4	156.50
20	.03196	323.4	98.50
22	.02535	514.2	61.96

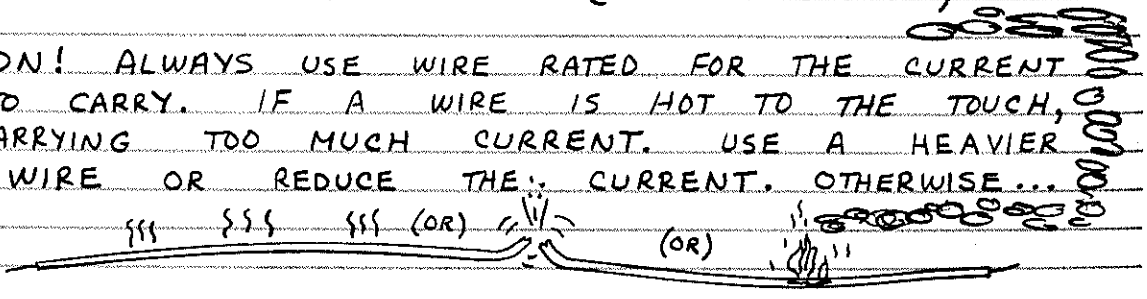
28	.01264	2067.0	15.41
30	.01003	3287.0	9.69

CABLES HAVE ONE OR MORE CONDUCTORS AND MORE INSULATION THAN ORDINARY WIRE. COAXIAL CABLE CAN CARRY HIGH FREQUENCY SIGNALS (LIKE TELEVISION).

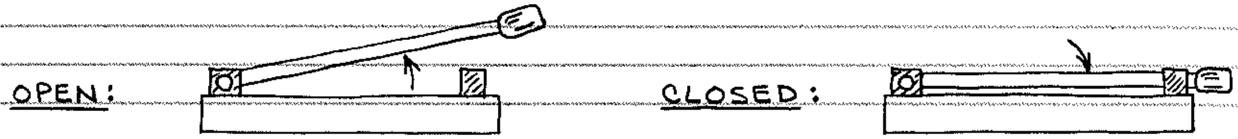
☐ CAUTION! ALWAYS USE WIRE RATED FOR THE CURRENT IT IS TO CARRY. IF A WIRE IS HOT TO THE TOUCH, IT'S CARRYING TOO MUCH CURRENT. USE A HEAVIER GAUGE WIRE OR REDUCE THE CURRENT. OTHERWISE...

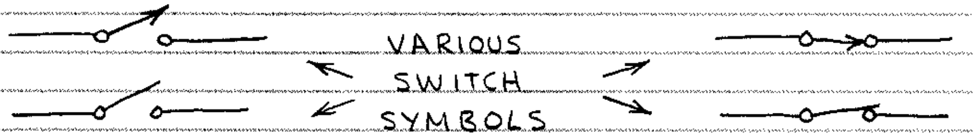


SWITCHES

MECHANICAL SWITCHES PERMIT OR INTERRUPT THE FLOW OF CURRENT. THEY ARE ALSO USED TO DIRECT CURRENT TO VARIOUS POINTS.

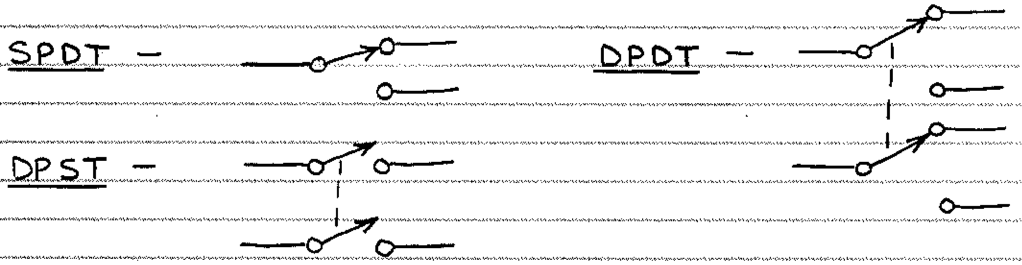
☐ THE BASIC KNIFE SWITCH — THE SIMPLEST SWITCH ...





THIS IS CALLED AN SPST (SINGLE-POLE, SINGLE-THROW) SWITCH.

☐ MULTIPLE CONTACT SWITCHES — HERE ARE SYMBOLS FOR THE MAJOR KINDS:

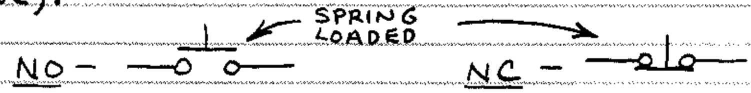


SPDT - SINGLE-POLE, DOUBLE-THROW
DPST - DOUBLE-POLE, SINGLE-THROW
DPDT - DOUBLE-POLE, DOUBLE-THROW

(THE DASHED LINE MEANS BOTH SIDES MOVE TOGETHER.)

☐ OTHER SWITCHES —

PUSHBUTTON. USUALLY SPST, NORMALLY OPEN (NO) OR NORMALLY CLOSED (NC).



ROTARY. WAFER-LIKE WITH ONE POLE AND 2 OR MORE CONTACTS. WAFERS CAN BE STACKED TO PROVIDE MORE POLES. MANY VARIATIONS ARE POSSIBLE.

MERCURY. MERCURY BLOB CLOSES SWITCH. POSITION SENSITIVE.

OTHER. MANY KINDS OF TOGGLE, ROCKER, LEVER, SLIDE, PUSH-ON/PUSH-OFF, ILLUMINATED AND OTHER SWITCHES ARE AVAILABLE.

RELAYS

A RELAY IS AN ELECTROMAGNETIC SWITCH. A SMALL CURRENT FLOWING THROUGH A COIL IN THE RELAY CREATES A MAGNETIC FIELD THAT PULLS ONE SWITCH CONTACT AGAINST OR AWAY FROM ANOTHER.

MICROPHONES AND SPEAKERS

A MICROPHONE CONVERTS SOUND WAVE VARIATIONS INTO CORRESPONDING VARIATIONS IN AN ELECTRICAL CURRENT. THE SOUND WAVE VARIATIONS ARE FIRST CONVERTED TO BACK-AND-FORTH MOVEMENTS OF A FLEXIBLE FILM OR FOIL CALLED A DIAPHRAGM. THESE MOVEMENTS THEN CAUSE VARIATIONS IN AN ELECTRICAL CURRENT BY ANY OF THE FOLLOWING MEANS:

☐ CARBON— MOVEMENT OF THE DIAPHRAGM CHANGES THE PRESSURE APPLIED TO A CAPSULE OF CARBON PARTICLES. THIS CAUSES PROPORTIONAL CHANGES IN THE RESISTANCE OF THE CAPSULE.

☐ DYNAMIC— A SMALL COIL IS MOVED THROUGH A MAGNETIC FIELD AS THE DIAPHRAGM MOVES. THIS CAUSES A PROPORTIONAL OUTPUT CURRENT TO BE GENERATED.

☐ CONDENSER— THE MOVING DIAPHRAGM ALTERS THE DISTANCE BETWEEN TWO METAL PLATES. THE RESULT IS A PROPORTIONAL CHANGE IN THE CAPACITANCE OF THE PLATES.

☐ CRYSTAL— A WAFER OF PIEZOELECTRIC MATERIAL (WHICH PRODUCES A VOLTAGE WHEN BENT BY THE PRESSURE OF SOUND WAVES) FORMS THE DIAPHRAGM OR IS MECHANICALLY LINKED TO THE DIAPHRAGM.

A SPEAKER CONVERTS VARIATIONS IN A CURRENT OR VOLTAGE INTO SOUND WAVES. THE TWO MOST COMMON SPEAKERS ARE:

☐ MAGNETIC— SIMILAR IN PRINCIPLE TO A DYNAMIC MICROPHONE. IN FACT, A MAGNETIC SPEAKER CAN BE USED AS A MICROPHONE.

☐ CRYSTAL— SIMILAR IN PRINCIPLE TO A CRYSTAL MICROPHONE. A CRYSTAL SPEAKER CAN DOUBLE AS A MICROPHONE.

RESISTORS

RESISTORS COME IN DOZENS OF SIZES AND SHAPES BUT THEY ALL DO THE SAME THING: LIMIT* CURRENT. MORE ABOUT THAT LATER. FIRST, LET'S SEE HOW A TYPICAL RESISTOR IS MADE:

*OR RESIST

CARBON COMPOSITION

COLOR CODE BANDS

"CARBON COMPOSITION" IS JUST A FANCY WAY OF DESCRIBING POWDERED CARBON MIXED WITH A GLUE-LIKE BINDER. THIS KIND OF RESISTOR IS EASY TO MAKE. AND ITS RESISTANCE CAN BE CHANGED FROM ONE RESISTOR TO THE NEXT SIMPLY BY CHANGING THE RATIO OF CARBON PARTICLES TO BINDER. MORE CARBON GIVES LESS RESISTANCE.

☐ DO-IT-YOURSELF RESISTORS — YOU CAN MAKE A RESISTOR BY DRAWING A LINE WITH A SOFT LEAD PENCIL ON A SHEET OF PAPER. MEASURE THE RESISTANCE OF THE LINE OR POINTS ALONG IT BY TOUCHING THE PROBES OF A MULTIMETER TO THE LINE. BE SURE TO SET THE MULTIMETER TO ITS HIGHEST RESISTANCE SCALE. THE RESISTANCE OF A SINGLE LINE MAY BE TOO HIGH TO MEASURE. IF SO, DRAW OVER THE LINE A DOZEN OR SO TIMES. HERE'S WHAT I MEASURED:

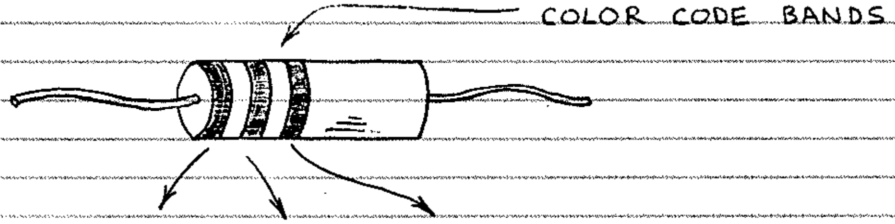
1,800,000 OHMS
3,460,000 OHMS
PROBE

☐ RESISTOR COLOR CODE — SEE THOSE COLOR CODE BANDS ON THE RESISTOR PICTORIAL? IN REAL LIFE THEY'RE KIND OF PRETTY. BUT THEY HAVE A FAR MORE IMPORTANT PURPOSE: THEY INDICATE THE RESISTANCE OF THE RESISTOR THEY DECORATE. HERE'S HOW:



COLOR	1	2	3 (MULTIPLIER)
BLACK	0	0	1
BROWN	1	1	10
RED	2	2	100
ORANGE	3	3	1,000
YELLOW	4	4	10,000
GREEN	5	5	100,000
BLUE	6	6	1,000,000
VIOLET	7	7	10,000,000
GRAY	8	8	100,000,000
WHITE	9	9	(NONE)

NOTE: SOMETIMES THERE'S A FOURTH BAND. IT INDICATES THE TOLERANCE* OF THE RESISTOR:

GOLD = ±5%
SILVER = ±10%
NONE = ±20%

* OR ACCURACY

LOOKS COMPLICATED THE FIRST TIME... BUT YOU'LL QUICKLY LEARN HOW TO USE IT. FOR EXAMPLE, WHAT'S THE RESISTANCE OF A RESISTOR COLOR CODED YELLOW, VIOLET AND RED? YELLOW IS THE FIRST COLOR SO THE FIRST NUMBER IS 4. VIOLET IS THE SECOND COLOR SO THE SECOND NUMBER IS 7. SINCE THE THIRD COLOR IS RED, THE MULTIPLIER IS 100. THEREFORE, THE RESISTANCE IS 47 × 100 OR 4700 OHMS. NO FOURTH COLOR BAND MEANS THE ACTUAL RESISTANCE IS 4700 ± 20%. 20% OF 4700 IS 940. THEREFORE, THE ACTUAL VALUE IS BETWEEN 3760 AND 5640 OHMS.

☐ SUBSTITUTING RESISTORS — WHAT IF YOU NEED A 6700-OHM RESISTOR BUT CAN ONLY FIND A 6800-OHM UNIT? YOU CAN ALMOST ALWAYS USE ANY VALUE WITHIN 10 OR 20% OF THE REQUIRED VALUE SO GO AHEAD AND USE IT. IF A PARTICULAR CIRCUIT REQUIRES MORE ACCURACY IT WILL TELL YOU. OF COURSE YOU CAN BUILD UP CUSTOM RESISTANCES BY CONNECTING TWO OR MORE RESISTORS IN SERIES OR IN PARALLEL. MORE ABOUT THAT LATER.

☐ RESISTOR SUBSTITUTION PRECAUTIONS — RESISTORS THAT CONDUCT LOTS OF CURRENT CAN BECOME VERY HOT! THEREFORE, ALWAYS USE RESISTORS HAVING THE PROPER POWER RATING. IF A PROJECT YOU'RE BUILDING DOESN'T SPECIFY THE POWER RATING FOR ITS RESISTORS, IT'S USUALLY OK TO USE 1/4 OR 1/2 WATT UNITS.

☐ SOME RESISTOR SHORTHAND — OFTEN YOU'LL SEE RESISTORS DESIGNATED WITH A K OR M SUFFIX, LIKE 47K OR 10M. K MEANS KILO, AFTER THE GREEK WORD FOR 1,000. THEREFORE, 47K MEANS 47 × 1,000 OR 47,000. M IS SHORT FOR MEGOHM OR 1,000,000 OHMS. THEREFORE A 1M RESISTOR HAS A RESISTANCE OF 1 × 1,000,000 OR 1,000,000 OHMS. SUMMING UP...

K = × 1,000 (47K = 47 × 1,000 = 47,000 OHMS)

M = × 1,000,000 (2.2M = 2.2 × 1,000,000 = 2,200,000 OHMS)

☐ OTHER KINDS OF RESISTORS — THE CARBON COMPOSITION RESISTOR IS ONLY ONE OF SEVERAL MAJOR KINDS OF RESISTORS. HERE ARE OTHERS:

METAL FILM RESISTORS. VARIOUS KINDS OF RESISTORS THAT USE A THIN FILM OF METAL OR A METAL PARTICLE MIXTURE TO ACHIEVE VARIOUS RESISTANCES.

CARBON FILM RESISTORS. THESE ARE MADE BY DEPOSITING A CARBON FILM ON A SMALL CERAMIC CYLINDER. A SPIRAL GROOVE CUT INTO THE FILM CONTROLS THE LENGTH OF CARBON BETWEEN THE LEADS, HENCE THE RESISTANCE.

WIRE-WOUND RESISTORS. THESE CONSIST OF A TUBULAR FORM WRAPPED WITH COILS OF RESISTANCE WIRE. THEY ARE VERY ACCURATE AND CAN TAKE LOTS OF HEAT.

PHOTORESISTORS. ALSO CALLED PHOTOCELLS. MADE FROM A LIGHT SENSITIVE MATERIAL LIKE CADMIUM SULFIDE. INCREASING THE LIGHT LEVEL DECREASES THE RESISTANCE. MORE ABOUT THIS LATER.

THERMISTORS. THIS IS A TEMPERATURE SENSITIVE RESISTOR. INCREASING THE TEMPERATURE DECREASES THE RESISTANCE (IN MOST CASES).

☐ VARIABLE RESISTORS — OFTEN IT'S NECESSARY TO CHANGE THE RESISTANCE OF A RESISTOR. VARIABLE RESISTORS ARE CALLED *POTENTIOMETERS*. THEY ARE USED TO ALTER THE VOLUME OF A RADIO, CHANGE THE BRIGHTNESS OF A LAMP, ADJUST THE CALIBRATION OF A METER, ETC. *TRIMMERS* ARE POTENTIOMETERS EQUIPPED WITH A PLASTIC THUMBWHEEL OR A SLOT FOR A SCREWDRIVER BLADE. THEY ARE DESIGNED FOR OCCASIONAL ADJUSTMENT.

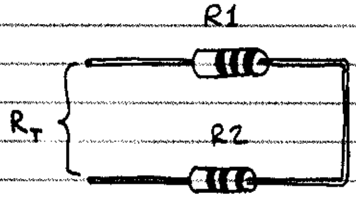
HOW RESISTORS ARE USED

☐ SERIES CIRCUIT — OFTEN RESISTORS ARE CONNECTED IN SERIES LIKE THIS:

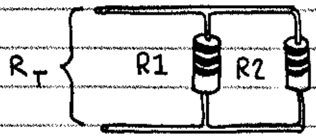
THE *TOTAL* RESISTANCE IS SIMPLY THE *SUM* OF THE INDIVIDUAL RESISTANCES.



$$R_T = R1 + R2$$

☐ PARALLEL CIRCUIT — RESISTORS CAN ALSO BE CONNECTED IN PARALLEL LIKE THIS:

THE *TOTAL* RESISTANCE IS THE PRODUCT OF THE TWO RESISTANCES DIVIDED BY THEIR SUM.

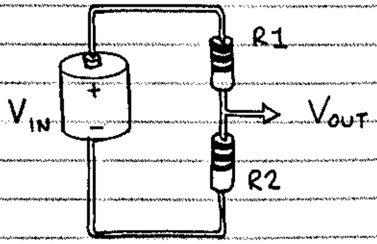


$$R_T = \frac{R1 \times R2}{R1 + R2}$$

FOR THREE OR MORE IN PARALLEL, GO FIND YOUR CALCULATOR BECAUSE...

$$R_T = \frac{1}{\frac{1}{R1} + \frac{1}{R2} + \frac{1}{R3} \ldots \text{ETC.}}$$

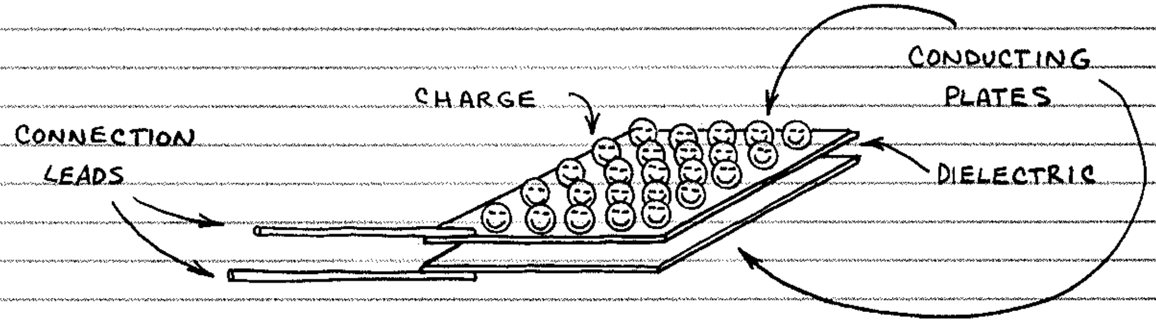
☐ VOLTAGE DIVISION — SUPER IMPORTANT! V_{OUT} IS DETERMINED BY RATIO OF R1 AND R2. HERE'S THE FORMULA:



$$V_{OUT} = V_{IN} \left(\frac{R2}{R1 + R2} \right)$$

CAPACITORS

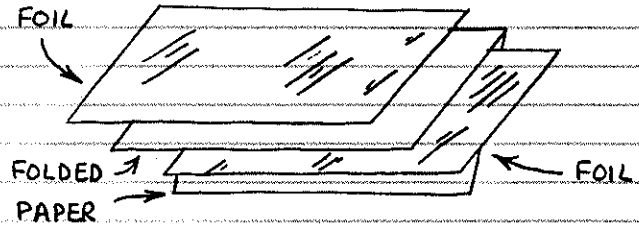
THERE ARE MANY KINDS OF CAPACITORS, BUT THEY ALL DO THE SAME THING: STORE ELECTRONS. THE SIMPLEST CAPACITOR IS TWO CONDUCTORS SEPARATED BY AN INSULATING MATERIAL CALLED THE DIELECTRIC. LIKE THIS:



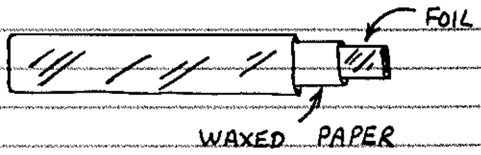
THE DIELECTRIC CAN BE PAPER, PLASTIC FILM, MICA, GLASS, CERAMIC, AIR OR A VACUUM. THE PLATES CAN BE ALUMINUM DISCS, ALUMINUM FOIL OR A THIN FILM OF METAL APPLIED TO OPPOSITE SIDES OF A SOLID DIELECTRIC. THE CONDUCTOR – DIELECTRIC – CONDUCTOR SANDWICH CAN BE ROLLED INTO A CYLINDER OR LEFT FLAT. MORE ABOUT TYPES OF CAPACITORS LATER.

HOW TO MAKE A CAPACITOR

YOU CAN MAKE A CAPACITOR FROM TWO SHEETS OF ALUMINUM FOIL AND ONE SHEET OF WAXED PAPER. FOLD THE PAPER AROUND ONE FOIL SHEET AND STACK THE SHEETS LIKE THIS:

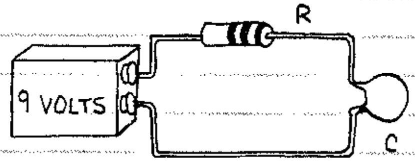


THEN FOLD THE SHEETS LIKE THIS:

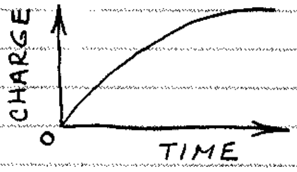


BE SURE THE FOIL SHEETS DON'T TOUCH! PRESS THE CONTACTS OF A 9-VOLT BATTERY BRIEFLY TO THE EXPOSED ENDS OF THE FOIL SHEETS. THEN TOUCH THE PROBES OF A HIGH-IMPEDANCE MULTIMETER TO THE FOIL SHEETS. THE METER WILL INDICATE A SMALL VOLTAGE FOR A FEW SECONDS. THE VOLTAGE WILL THEN FALL TO ZERO.

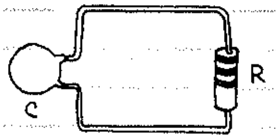
☐ CHARGING A CAPACITOR — THE MINUS SIDE OF OUR HOMEMADE CAPACITOR IS CHARGED WITH ELECTRONS ALMOST IMMEDIATELY. SINCE RESISTORS LIMIT CURRENT YOU CAN SLOW DOWN THE CHARGING TIME BY PLACING A RESISTOR BETWEEN THE CAPACITOR AND THE 9-VOLT BATTERY:



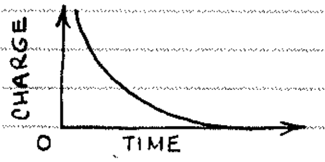
HERE'S A GRAPH OF THE CHARGING TIME:



☐ DISCHARGING A CAPACITOR — THE ELECTRONS IN A CHARGED CAPACITOR WILL GRADUALLY LEAK THROUGH THE DIELECTRIC UNTIL BOTH PLATES HAVE AN EQUAL CHARGE. THE CAPACITOR IS THEN DISCHARGED. THE CAPACITOR CAN BE DISCHARGED VERY QUICKLY BY CONNECTING ITS PLATES TOGETHER. OR IT CAN BE DISCHARGED MORE SLOWLY BY CONNECTING A RESISTOR ACROSS IT:



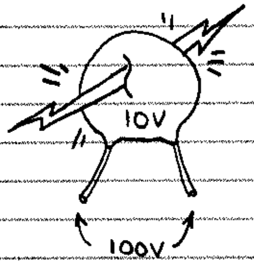
HERE'S A GRAPH OF THE DISCHARGE TIME:



☐ SPECIFYING CAPACITORS — THE ABILITY TO STORE ELECTRONS IS KNOWN AS CAPACITANCE. CAPACITANCE IS SPECIFIED IN FARADS. A 1-FARAD CAPACITOR CONNECTED TO A 1-VOLT SUPPLY WILL STORE 6,280,000,000,000,000,000 (6.28×10^{18}) ELECTRONS! MOST CAPACITORS HAVE MUCH SMALLER VALUES. SMALL CAPACITORS ARE SPECIFIED IN PICOFARADS (TRILLIONTHS OF A FARAD) AND LARGER CAPACITORS ARE SPECIFIED IN MICROFARADS (MILLIONTHS OF A FARAD). SUMMING UP:

1-FARAD = 1 F
1-MICROFARAD = $1\,\mu F = 10^{-6}\,F = 0.000\,001\,F$
1-PICOFARAD = $1\,pF = 10^{-12}\,F = 0.000\,000\,000\,001\,F$

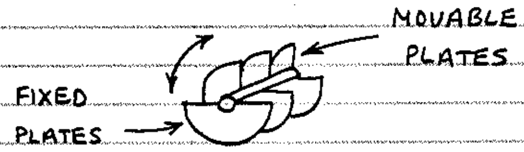
☐ SUBSTITUTING CAPACITORS — THE CAPACITANCE SPECIFIED FOR MOST CAPACITORS MAY BE FROM 5 TO 100 % AWAY FROM THE ACTUAL VALUE. THEREFORE YOU CAN OFTEN SUBSTITUTE CLOSE VALUES FOR A SPECIFIED VALUE. BE SURE, HOWEVER, TO USE A CAPACITOR RATED AT THE EXPECTED MAXIMUM VOLTAGE LEVEL!



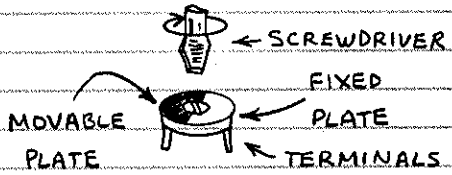
☐ CAPACITOR SUBSTITUTION PRECAUTIONS — YOU MUST MAKE SURE THE CAPACITOR YOU PLAN TO USE MEETS OR EXCEEDS THE REQUIRED VOLTAGE RATING. OTHERWISE ITS DIELECTRIC MAY BE ZAPPED BY THE STORED CHARGE. THE VOLTAGE RATING IS USUALLY PRINTED ON THE CAPACITOR. V MEANS VOLTS. WV IS WORKING VOLTS (SAME THING).

☐ KINDS OF CAPACITORS — CAPACITORS ARE OFTEN LABELED ACCORDING TO THEIR DIELECTRIC. THUS YOU'LL SEE REFERENCES TO CERAMIC, MICA, POLYSTYRENE AND MANY OTHERS. ALL THESE ARE FIXED VALUE CAPACITORS. SOME CAPACITORS HAVE A VARIABLE CAPACITY AND A SPECIAL CLASS OF FIXED CAPACITORS HAS MUCH MORE CAPACITY THAN OTHER CAPACITORS. HERE'S MORE:

VARIABLE CAPACITORS. THESE USUALLY HAVE ONE OR MORE NON-MOVING PLATES AND ONE OR MORE MOVING PLATES. THE CAPACITANCE IS CHANGED BY ROTATING A ROD AFFIXED TO ONE SIDE OF THE MOVABLE PLATES.

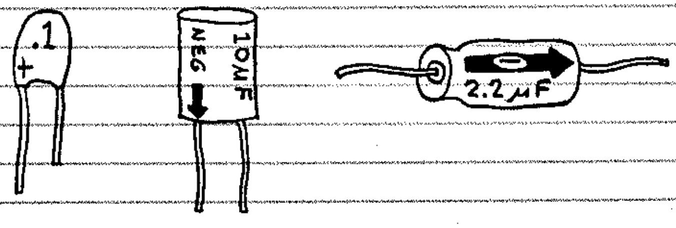


THIS KIND IS USED TO TUNE RADIO RECEIVERS AND TRANSMITTERS. THE DIELECTRIC IS USUALLY AIR.



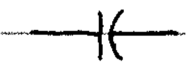
THIS KIND IS USED TO TUNE OSCILLATORS LIKE THOSE USED IN DIGITAL WATCHES. THEY'RE SMALL.

ELECTROLYTIC CAPACITORS. UNIQUE IN THAT A THIN OXIDE LAYER FORMED ON ALUMINUM OR TANTALUM FOIL IS THE DIELECTRIC. MUCH HIGHER CAPACITANCE THAN NON-ELECTROLYTIC TYPES. TANTALUM UNITS HAVE MORE CAPACITANCE PER VOLUME AND A LONGER LIFE THAN ALUMINUM ELECTROLYTICS. BUT THEY COST MORE. MOST ELECTROLYTICS ARE POLARIZED. THEY MUST BE CONNECTED INTO A CIRCUIT IN THE PROPER DIRECTION:

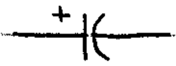


POSITIVE LEAD MUST GO TO MOST POSITIVE CONNECTION POINT!

☐ CAPACITOR SYMBOLS:

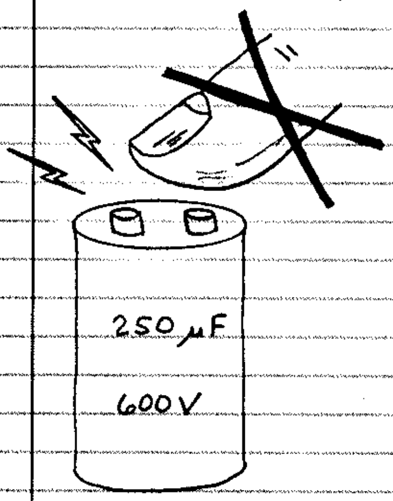


FIXED

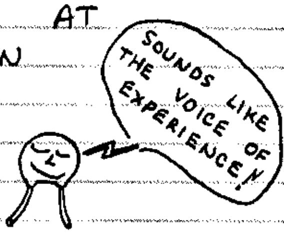


FIXED

VARIABLE



☐ WARNING! CAPACITORS CAN STORE A CHARGE FOR A CONSIDERABLE TIME AFTER THE POWER TO THEM HAS BEEN SWITCHED OFF. THIS CHARGE CAN BE DANGEROUS! A LARGE ELECTROLYTIC CHARGED TO ONLY 5 OR 10 VOLTS CAN MELT THE TIP OF A SCREWDRIVER PLACED ACROSS ITS TERMINALS! HIGH VOLTAGE CAPACITORS LIKE THOSE USED IN TELEVISION SETS AND PHOTOFLASH UNITS CAN STORE A LETHAL CHARGE! NEVER TOUCH THE LEADS OF SUCH A CAPACITOR. AT THE VERY LEAST THE JOLT CAN THROW YOU ACROSS A ROOM!

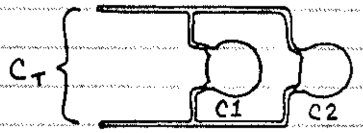


SOUNDS LIKE THE VOICE OF EXPERIENCE!

HOW CAPACITORS ARE USED

☐ PARALLEL CIRCUIT — OFTEN CAPACITORS ARE CONNECTED IN PARALLEL LIKE THIS:

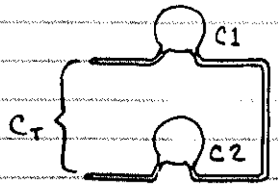
THE TOTAL CAPACITANCE IS THE SUM OF THE INDIVIDUAL CAPACITANCES.



$$C_T = C1 + C2$$

☐ SERIES CIRCUIT — SOMETIMES CAPACITORS ARE CONNECTED IN SERIES LIKE THIS:

THE TOTAL CAPACITANCE IS THE PRODUCT OF THE TWO CAPACITANCES DIVIDED BY THEIR SUM.



$$C_T = \frac{C1 \times C2}{C1 + C2}$$

THREE OR MORE CAPACITORS IN SERIES? HERE'S THE FORMULA:

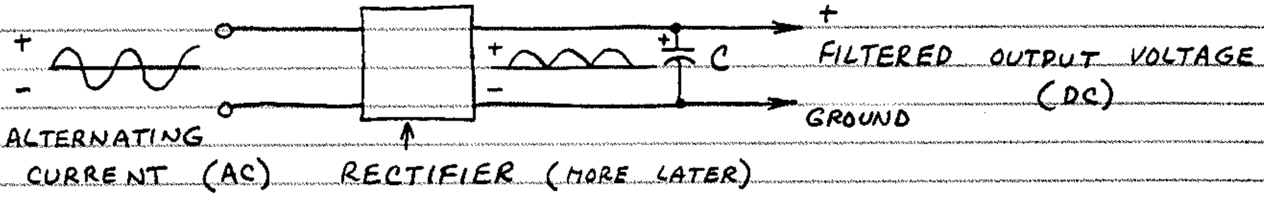
$$C_T = \frac{1}{\frac{1}{C1} + \frac{1}{C2} + \frac{1}{C3} \ldots \text{ETC.}}$$

☐ AND MORE — THERE ARE MANY OTHER WAYS TO USE CAPACITORS, SOME OF WHICH ARE SHOWN NEXT...

RESISTOR AND CAPACITOR APPLICATIONS

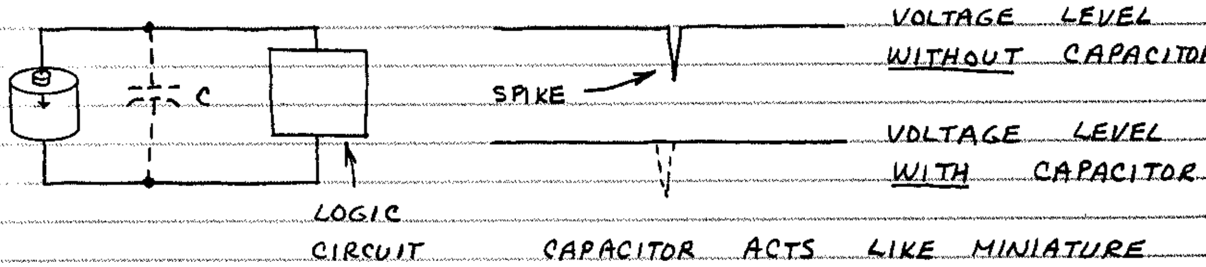
RESISTORS AND CAPACITORS ARE THE KEY INGREDIENTS OF MANY ELECTRONIC CIRCUITS. HERE ARE SOME REASONS WHY:

☐ POWER SUPPLY FILTER — A CAPACITOR WILL SMOOTH (FILTER) THE PULSATING VOLTAGE FROM A POWER SUPPLY INTO A STEADY DIRECT CURRENT (DC).



+
-
+
-
C
+
FILTERED OUTPUT VOLTAGE (DC)
GROUND
ALTERNATING CURRENT (AC)
RECTIFIER (MORE LATER)

☐ SPIKE REMOVER — DIGITAL LOGIC CIRCUITS, WHICH WE'LL FIND OUT MORE ABOUT LATER, CAN USE LOTS OF CURRENT MOMENTARILY WHEN THEY SWITCH FROM OFF TO ON OR VICE VERSA. THIS CAN CAUSE VERY BRIEF BUT SUBSTANTIAL REDUCTIONS IN POWER APPLIED TO NEARBY CIRCUITS. THESE POWER SPIKES (OR GLITCHES, AS THEY ARE SOMETIMES CALLED) CAN BE ELIMINATED BY PLACING A SMALL (0.1 μF) CAPACITOR ACROSS THE POWER LEADS OF THE LOGIC CIRCUIT:

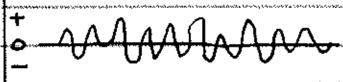


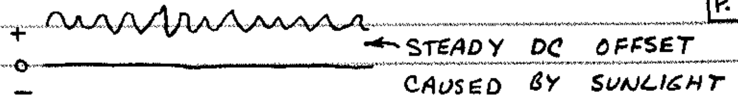
C
LOGIC CIRCUIT
SPIKE
VOLTAGE LEVEL WITHOUT CAPACITOR
VOLTAGE LEVEL WITH CAPACITOR

CAPACITOR ACTS LIKE MINIATURE BATTERY THAT SUPPLIES POWER DURING THE SPIKE.

☐ AC-DC SELECTIVE FILTER — OFTEN AN ELECTRICAL SIGNAL WILL BE RIDING ATOP A STEADY DC SIGNAL. FOR EXAMPLE, THE SIGNAL FROM A LIGHTWAVE COMMUNICATION SYSTEM MAY LOOK LIKE THIS WHEN IT'S DARK: BUT SUNLIGHT CAUSES THIS:

P. 123





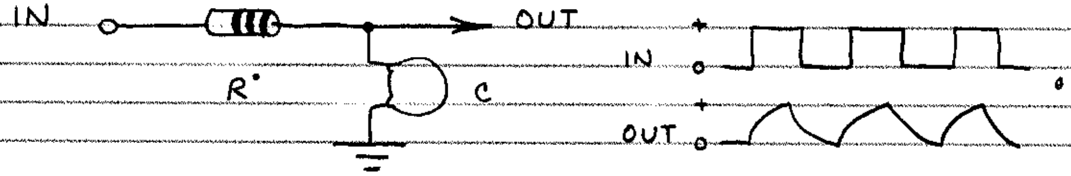
+
0
-
STEADY DC OFFSET CAUSED BY SUNLIGHT

A CAPACITOR WILL PASS THE FLUCTUATING SIGNAL AND COMPLETELY BLOCK THE STEADY DC LEVEL.

☐ R-C CIRCUITS — TWO CIRCUITS THAT COMBINE A RESISTOR (R) AND CAPACITOR (C) ARE VERY IMPORTANT. THEY ARE THE INTEGRATOR AND DIFFERENTIATOR. BOTH THESE CIRCUITS ARE USED TO RESHAPE AN INCOMING STREAM OF WAVES OR PULSES.

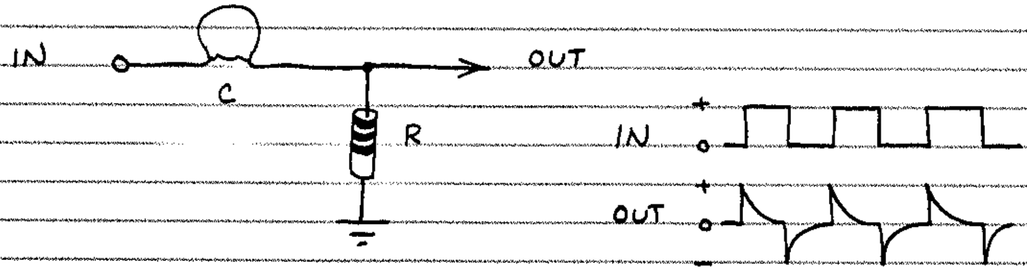
THE PRODUCT OF R AND C IN THESE CIRCUITS IS CALLED THE RC TIME CONSTANT. FOR THE CIRCUITS SHOWN BELOW, THE RC TIME CONSTANT (IN SECONDS) IS AT LEAST TEN TIMES THE INTERVAL BETWEEN INCOMING CYCLES OR PULSES.

1. INTEGRATOR. HERE'S A BASIC RC INTEGRATOR:



IF THE INPUT PULSES ARE SPEEDED UP, THE OUTPUT WAVEFORMS (OFTEN CALLED A SAWTOOTH) WILL NOT REACH THEIR FULL HEIGHT (AMPLITUDE). IT'S EASY TO DESIGN AN AMPLIFIER THAT IGNORES WAVES WITH LESS THAN A DESIRED AMPLITUDE. THEREFORE, THE INTEGRATOR CAN FUNCTION AS A FILTER WHICH PASSES ONLY SIGNALS BELOW A CERTAIN FREQUENCY.

2. DIFFERENTIATOR. HERE'S A BASIC RC DIFFERENTIATOR:



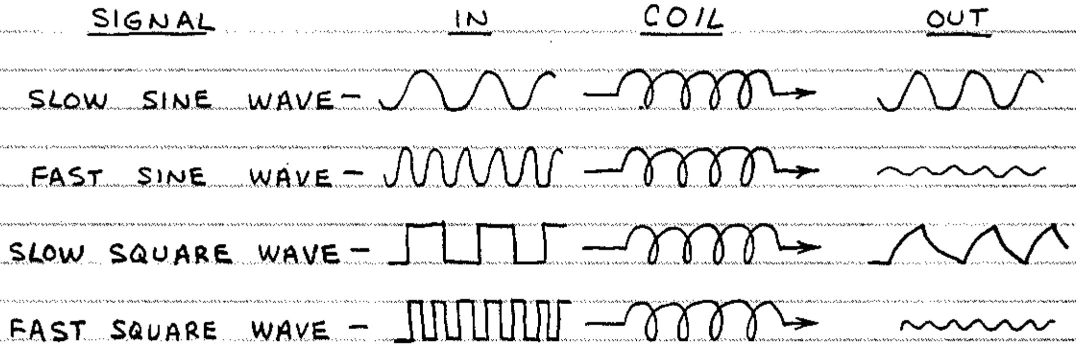
THIS CIRCUIT PRODUCES SYMMETRICAL OUTPUT WAVES WITH SHARP POSITIVE AND NEGATIVE PEAKS. IT'S USED TO MAKE NARROW PULSE GENERATORS FOR TELEVISION RECEIVERS AND TO TRIGGER DIGITAL LOGIC CIRCUITS.

☐ MORE ABOUT R-C — YOU WILL OFTEN SEE REFERENCES TO THE RC TIME CONSTANT OF A CIRCUIT. IT'S THE TIME IN SECONDS FOR A CHARGING OR DISCHARGING CAPACITOR TO GO THROUGH 63.3% OF THE CHANGE IN CHARGE.

COILS

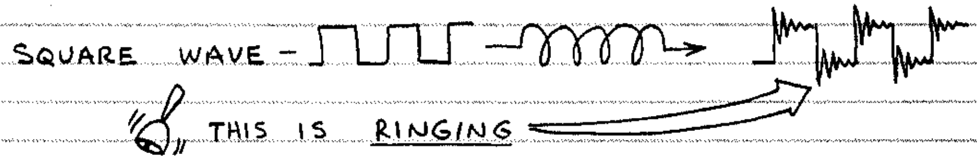
ELECTRONS MOVING THROUGH A WIRE CAUSE AN *ELECTROMAGNETIC FIELD* TO ENCIRCLE THE WIRE. AS YOU KNOW FROM CHAPTER 1, PASSING A CURRENT THROUGH A WIRE THAT'S BEEN WRAPPED AS A COIL (P. 15) CREATES AN EVEN STRONGER FIELD. THIS FIELD MAKES POSSIBLE SOLENOIDS, MOTORS AND ELECTROMAGNETS. COILS HAVE OTHER IMPORTANT ROLES, TOO:

1. COILS RESIST *RAPID* CHANGES IN THE CURRENT FLOWING THROUGH THEM WHILE FREELY PASSING STEADY (DC) CURRENT. HERE ARE SOME EXAMPLES:



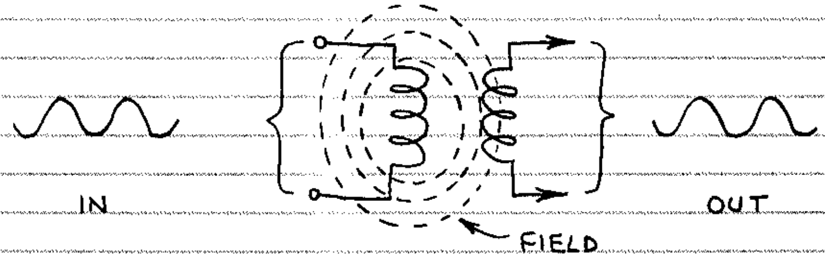
SIGNAL
IN
COIL
OUT
SLOW SINE WAVE -
FAST SINE WAVE -
SLOW SQUARE WAVE -
FAST SQUARE WAVE -

SOMETIMES A COIL WILL ADD *RINGING* TO A SQUARE WAVE PASSING THROUGH IT. THIS CAN HAPPEN WHEN THE RESISTANCE OF THE EXTERNAL CURRENT PATH THAT CONNECTS THE ENDS OF THE COIL IS HIGH.



SQUARE WAVE -
THIS IS RINGING

2. SOME OF THE ENERGY IN THE FIELD AROUND A COIL CAN BE *INDUCED* (TRANSFERRED) INTO A SECOND, NEARBY COIL. THIS IS THE PRINCIPLE OF THE *TRANSFORMER*:



IN
OUT
FIELD

THE INPUT SIDE OF THE TRANSFORMER IS CALLED THE *PRIMARY*. THE OUTPUT SIDE IS CALLED THE *SECONDARY*.

☐ TYPES OF COILS — THERE ARE MANY DIFFERENT TYPES OF COILS. HERE ARE SOME OF THEM:

TUNING COIL. RADIOS USE VARIOUS COILS TO HELP SELECT A DESIRED SIGNAL. TUNING COILS HAVE A SERIES OF TAPS OR A MOVABLE CORE SO THEIR INDUCTANCE*, HENCE RESONANT FREQUENCY, CAN BE CHANGED.

TYPICAL TUNING COIL

ANTENNA COIL. RADIOS OFTEN USE A BROADLY TUNED COIL TO PICK UP RADIO SIGNALS.

TYPICAL ANTENNA COIL

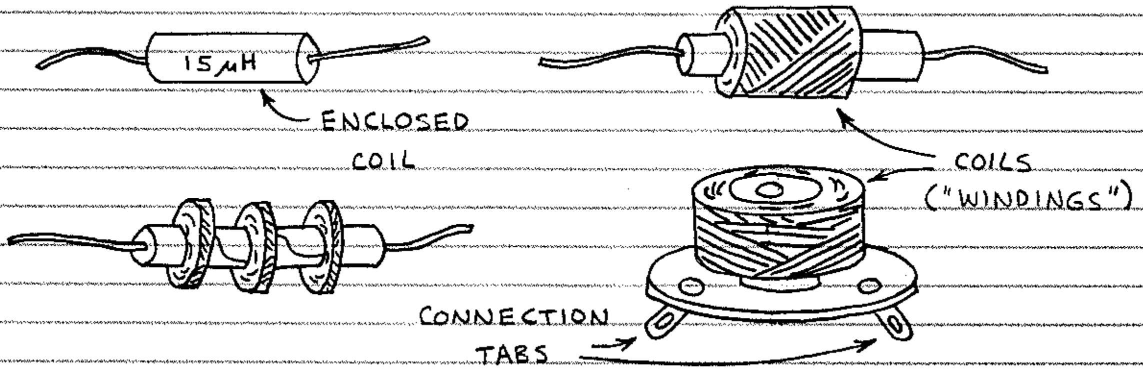
CHOKE. USED IN MANY CIRCUITS TO LIMIT OR SUPPRESS FLUCTUATING SIGNALS WHILE PASSING A STEADY CURRENT. CHOKES ARE AVAILABLE IN MANY SHAPES AND SIZES:



15 μH
ENCLOSED COIL
COILS ("WINDINGS")
CONNECTION TABS

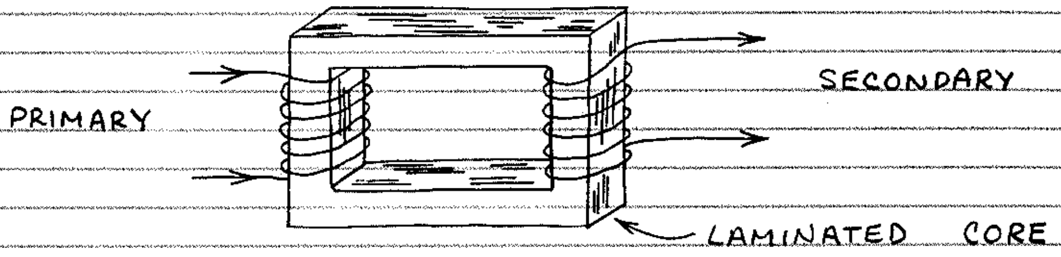
TRANSFORMER. SO IMPORTANT WE'LL DEVOTE A COMPLETE SECTION TO IT.

☐ APPLICATIONS FOR COILS — IN ADDITION TO THOSE ALREADY DESCRIBED, COILS ARE USED IN FILTERS THAT SELECTIVELY PASS SPECIFIC FREQUENCY BANDS.

☐ CAUTION! A HIGH VOLTAGE PULSE CAN BE PRODUCED IN A CHOKE WHEN THE CURRENT FLOWING THROUGH IT IS INTERRUPTED. BE CAREFUL.

TRANSFORMERS

TRANSFORMERS ARE A MAJOR CLASS OF COILS HAVING TWO OR MORE WINDINGS USUALLY WRAPPED AROUND A COMMON CORE MADE FROM LAMINATED IRON SHEETS. HERE'S A SIMPLE TRANSFORMER:

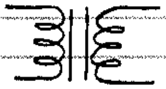


IF THE CURRENT FLOWING THROUGH THE PRIMARY COIL IS FLUCTUATING, THEN A CURRENT WILL BE INDUCED INTO THE SECONDARY WINDING. A STEADY (DC) CURRENT WILL NOT BE TRANSFERRED FROM ONE COIL TO THE OTHER.

☐ HOW THEY WORK — TRANSFORMERS HAVE THE ABILITY TO TRANSFORM VOLTAGE AND CURRENT TO HIGHER OR LOWER LEVELS. THEY DO NOT, OF COURSE, CREATE POWER FROM NOTHING. THEREFORE, IF A TRANSFORMER BOOSTS THE VOLTAGE OF A SIGNAL, IT REDUCES ITS CURRENT. AND IF IT CUTS THE VOLTAGE OF A SIGNAL, IT RAISES ITS CURRENT. IN OTHER WORDS... THE POWER FLOWING FROM A TRANSFORMER CANNOT EXCEED THE INCOMING POWER!

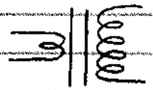
☐ TURNS RATIO — THE RATIO OF PRIMARY TO SECONDARY TURNS DETERMINES A TRANSFORMER'S VOLTAGE RATIO...

1:1 RATIO.



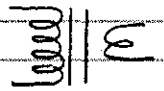
THE PRIMARY VOLTAGE AND CURRENT ARE TRANSFERRED UNALTERED TO THE SECONDARY. OFTEN CALLED AN ISOLATION TRANSFORMER.

STEP-UP.



THE VOLTAGE IS INCREASED BY THE TURNS RATIO. THUS A 1:5 TURNS RATIO WILL BOOST 5-VOLTS AT THE PRIMARY INTO 25-VOLTS AT THE SECONDAR

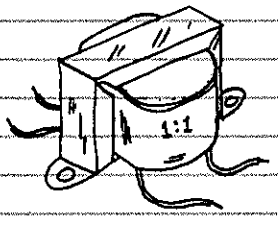
STEP-DOWN.



THE VOLTAGE IS REDUCED BY THE TURNS RATIO. THUS A 5:1 TURNS RATIO WILL DROP 25-VOLTS AT THE PRIMARY TO 5-VOLTS AT THE SECONDARY.

☐ TRANSFORMER TYPES AND APPLICATIONS — HERE ARE SOME OF THE MAJOR TRANSFORMER TYPES:

ISOLATION.



USED TO ISOLATE DIFFERENT PARTS OF A CIRCUIT AND TO PROVIDE PROTECTION FROM ELECTRICAL SHOCK.

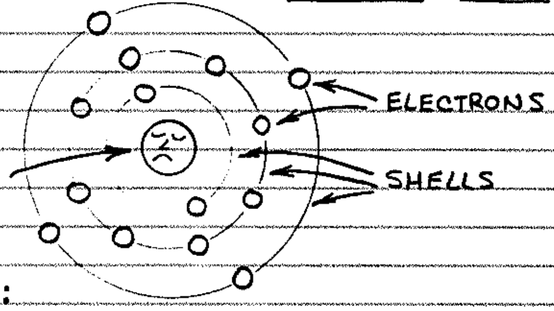
3. SEMICONDUCTORS

THE MOST EXCITING AND IMPORTANT ELECTRONIC COMPONENTS ARE MADE FROM CRYSTALS CALLED SEMICONDUCTORS. DEPENDING ON CERTAIN CONDITIONS, A SEMICONDUCTOR CAN ACT LIKE A CONDUCTOR OR AN INSULATOR.

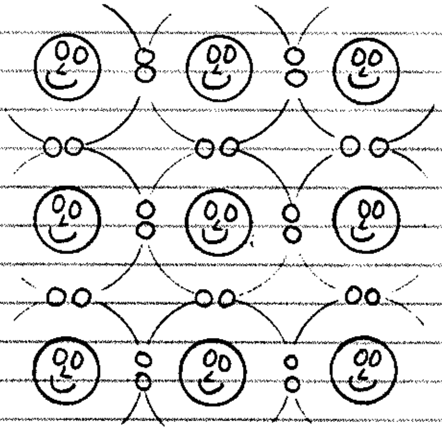
SILICON

THERE ARE MANY DIFFERENT SEMICONDUCTING MATERIALS, BUT SILICON, THE MAIN INGREDIENT OF SAND, IS THE MOST POPULAR.

SILICON ATOM



A SILICON ATOM HAS BUT FOUR ELECTRONS IN ITS OUTERMOST SHELL, BUT IT WOULD LIKE TO HAVE EIGHT. THEREFORE, A SILICON ATOM WILL LINK UP WITH FOUR OF ITS NEIGHBORS TO SHARE ELECTRONS:

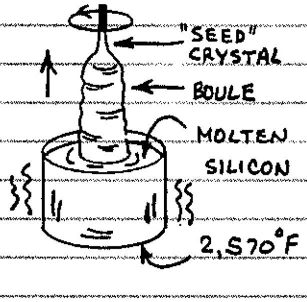


A CLUSTER OF SILICON ATOMS SHARING OUTER ELECTRONS FORMS A REGULAR ARRANGEMENT CALLED A CRYSTAL.

← THIS IS A MAGNIFIED VIEW OF A SILICON CRYSTAL. TO KEEP THINGS SIMPLE, ONLY THE OUTER ELECTRONS OF EACH ATOM ARE SHOWN.

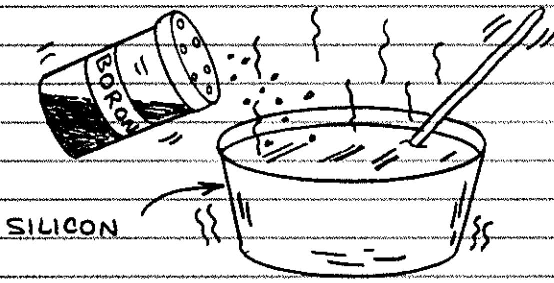
SILICON FORMS 27.7 % OF THE EARTH'S CRUST! ONLY OXYGEN IS MORE COMMON. IT'S NEVER FOUND IN THE PURE STATE. WHEN PURIFIED, IT'S DARK GRAY IN COLOR.

SILICON AND DIAMOND SHARE THE SAME CRYSTAL STRUCTURE AND OTHER PROPERTIES. BUT SILICON IS NOT TRANSPARENT.



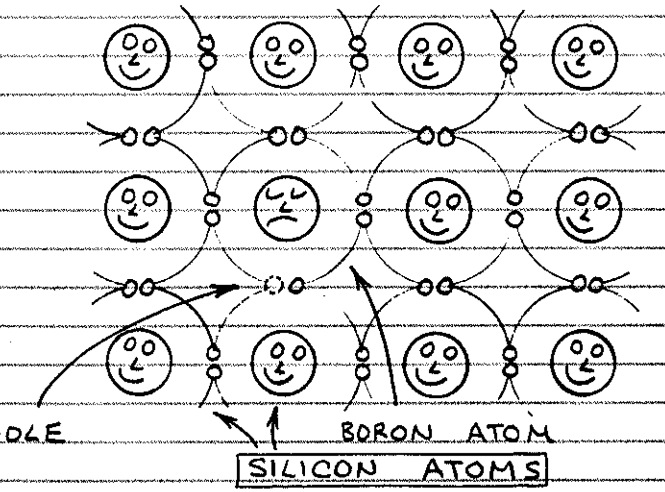
SILICON CAN BE GROWN INTO BIG CRYSTALS. IT'S CUT INTO WAFERS FOR MAKING ELECTRONIC PARTS.

☐ SILICON RECIPES— PURE SILICON ISN'T VERY USEFUL. THAT'S WHY SILICON MAKERS SPICE UP THEIR SILICON RECIPES WITH A DASH OF PHOSPHORUS, BORON OR OTHER GOODIES. THIS IS CALLED DOPING THE SILICON. WHEN GROWN INTO CRYSTALS, DOPED SILICON HAS VERY USEFUL ELECTRONIC PROPERTIES!

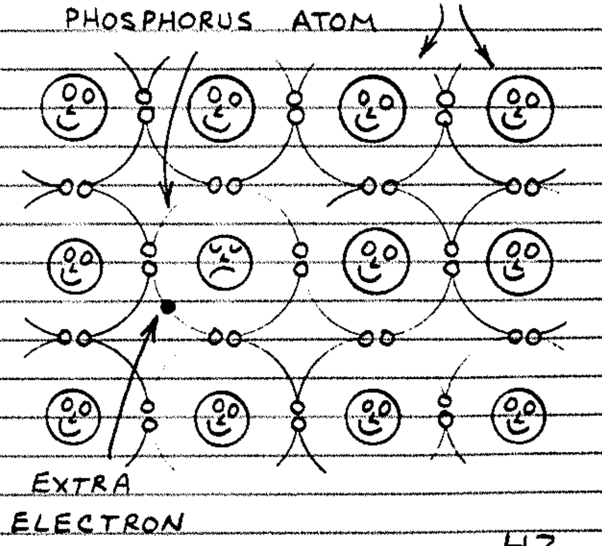


☐ P & N SPICED SILICON LOAF— BORON, PHOSPHORUS AND CERTAIN OTHER ATOMS CAN JOIN WITH SILICON ATOMS TO FORM CRYSTALS. HERS'S THE CATCH: A BORON ATOM HAS ONLY THREE ELECTRON IN ITS OUTER SHELL. AND A PHOSPHORUS ATOM HAS FIVE ELECTRONS IN ITS OUTER SHELL. SILICON WITH EXTRA PHOSPHORUS ELECTRONS IS CALLED N-TYPE SILICON (N = NEGATIVE). SILICON WITH ELECTRON DEFICIENT BORON ATOMS IS CALLED P-TYPE SILICON (P = POSITIVE).

☐ P-TYPE SILICON—
A BORON ATOM IN A CLUSTER OF SILICON ATOMS LEAVES A VACANT ELECTRON OPENING CALLED A HOLE. IT'S POSSIBLE FOR AN ELECTRON FROM A NEARBY ATOM TO "FALL" INTO THE HOLE. THEREFORE, THE HOLE HAS MOVED TO A NEW LOCATION. REMEMBER, HOLES CAN MOVE THROUGH SILICON (JUST AS BUBBLES MOVE THROUGH WATER).



☐ N-TYPE SILICON—
A PHOSPHORUS ATOM IN A CLUSTER OF SILICON ATOMS DONATES AN EXTRA ELECTRON. THIS EXTRA ELECTRON CAN MOVE THROUGH THE CRYSTAL WITH COMPARATIVE EASE. IN OTHER WORDS, N-TYPE SILICON CAN CARRY AN ELECTRICAL CURRENT. BUT SO CAN P-TYPE SILICON! HOLES "CARRY" THE CURRENT.



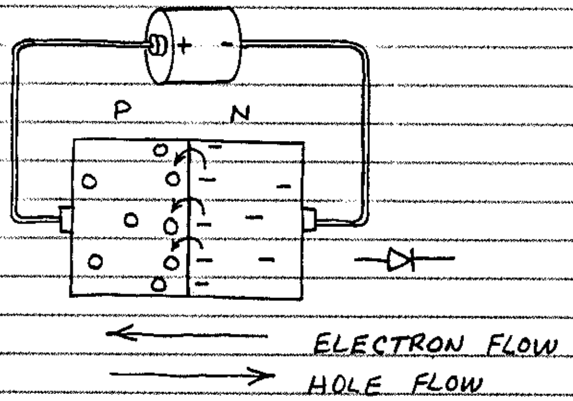
THE DIODE

BOTH P-TYPE AND N-TYPE SILICON CONDUCT ELECTRICITY. THE RESISTANCE OF BOTH TYPES IS DETERMINED BY THE PROPORTION OF HOLES OR SURPLUS ELECTRONS. THEREFORE BOTH TYPES CAN FUNCTION AS RESISTORS. AND THEY WILL CONDUCT ELECTRICITY IN ANY DIRECTION.

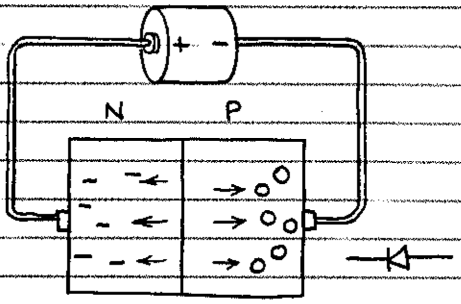
BY FORMING SOME P-TYPE SILICON IN A CHIP OF N-TYPE SILICON, ELECTRONS WILL FLOW THROUGH THE SILICON IN ONLY ONE DIRECTION. THIS IS THE PRINCIPLE OF THE DIODE. THE P-N INTERFACE IS CALLED THE PN JUNCTION.

☐ HOW THE DIODE WORKS — HERE'S A SIMPLIFIED EXPLANATION OF HOW A DIODE CONDUCTS ELECTRICITY IN ONE DIRECTION (FORWARD) WHILE BLOCKING THE FLOW OF CURRENT IN THE OPPOSITE DIRECTION (REVERSE).

FORWARD BIAS



REVERSE BIAS

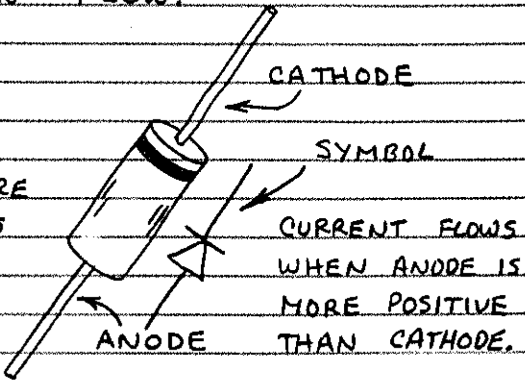


NO CURRENT FLOW

HERE THE CHARGE FROM THE BATTERY REPELS HOLES AND ELECTRONS TOWARD THE JUNCTION. IF THE VOLTAGE EXCEEDS 0.6-VOLT (SILICON), THEN ELECTRONS WILL CROSS THE JUNCTION AND COMBINE WITH HOLES. A CURRENT THEN FLOWS.

HERE THE CHARGE FROM THE BATTERY ATTRACTS HOLES AND ELECTRONS AWAY FROM THE JUNCTION. THEREFORE, NO CURRENT CAN FLOW.

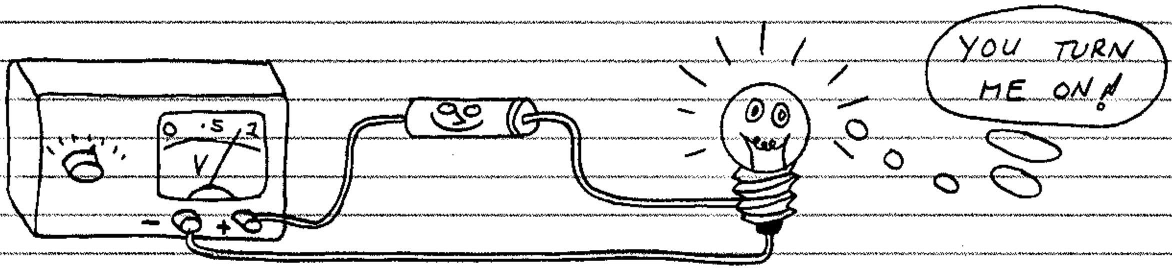
☐ A TYPICAL DIODE — DIODES ARE COMMONLY ENCLOSED IN SMALL GLASS CYLINDERS. A DARK BAND MARKS THE CATHODE TERMINAL. THE OPPOSITE TERMINAL IS THE ANODE

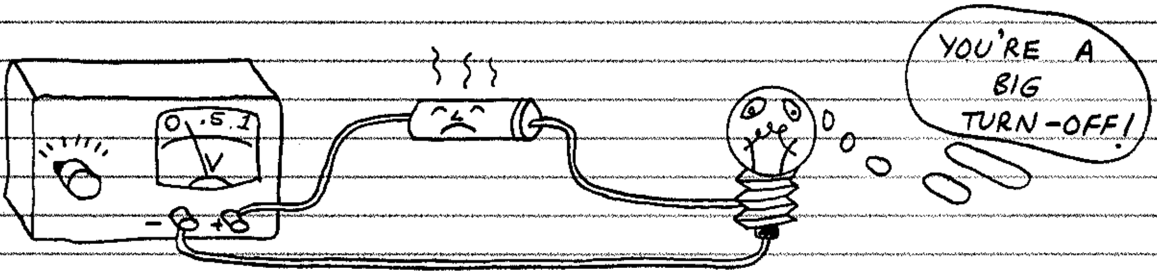


CURRENT FLOWS WHEN ANODE IS MORE POSITIVE THAN CATHODE.

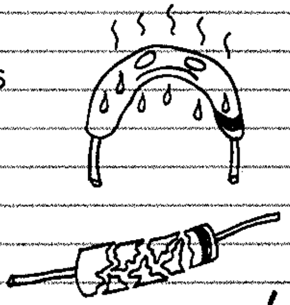
☐ DIODE OPERATION — YOU ALREADY KNOW A DIODE IS LIKE AN ELECTRONIC ONE-WAY VALVE. IT'S IMPORTANT TO UNDERSTAND SOME ADDITIONAL ASPECTS OF DIODE OPERATION. HERE ARE SOME KEY ONES:

1. A DIODE WILL NOT CONDUCT UNTIL THE FORWARD VOLTAGE REACHES A CERTAIN THRESHOLD POINT. FOR SILICON DIODES THIS VOLTAGE IS ABOUT 0.6-VOLT.





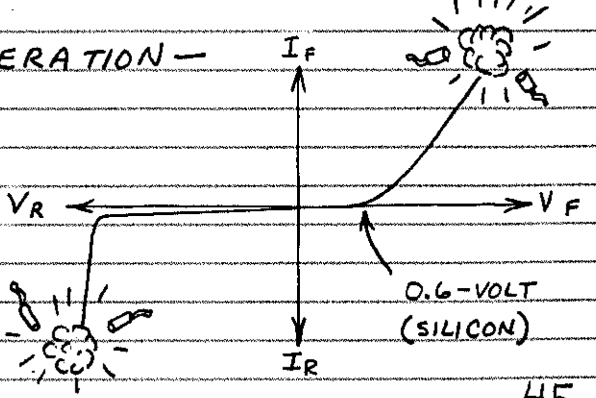
2. IF THE FORWARD CURRENT BECOMES EXCESSIVE, THE SEMICONDUCTOR CHIP MAY CRACK OR MELT! AND THE CONTACTS MAY SEPARATE. IF THE CHIP MELTS, THE DIODE MAY SUDDENLY CONDUCT IN BOTH DIRECTIONS. THE RESULTING HEAT MAY VAPORIZE THE CHIP!



3. TOO MUCH REVERSE VOLTAGE WILL CAUSE A DIODE TO CONDUCT IN THE WRONG DIRECTION. SINCE THIS VOLTAGE IS FAIRLY HIGH, THE SUDDEN CURRENT SURGE MAY ZAP THE DIODE.

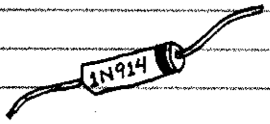
☐ SUMMING UP DIODE OPERATION — THIS GRAPH SUMS UP DIODE OPERATION. (IT'S APPROXIMATE.)

V_F = FORWARD VOLTAGE
V_R = REVERSE VOLTAGE
I_F = FORWARD CURRENT
I_R = REVERSE CURRENT



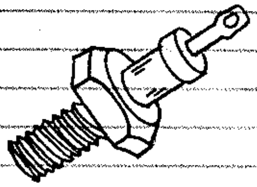
☐ TYPES OF DIODES — MANY DIFFERENT KINDS OF DIODES ARE AVAILABLE. HERE ARE SOME OF THE MAJOR TYPES:

SMALL SIGNAL.



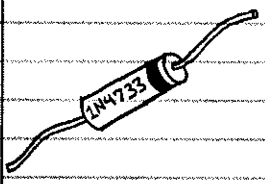
SMALL SIGNAL DIODES ARE USED TO TRANSFORM LOW CURRENT AC TO DC, DETECT (DEMODULATE) RADIO SIGNALS, MULTIPLY VOLTAGE, PERFORM LOGIC, ABSORB VOLTAGE SPIKES, ETC.

POWER RECTIFIER.



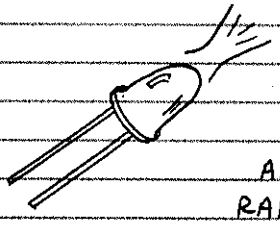
FUNCTIONALLY IDENTICAL TO SMALL SIGNAL DIODES, POWER RECTIFIERS CAN HANDLE *MUCH* MORE CURRENT. THEY ARE INSTALLED IN LARGE METAL PACKAGES THAT SOAK UP EXCESS HEAT AND TRANSFER IT TO A METAL HEAT SINK. USED MAINLY IN POWER SUPPLIES.

ZENER.



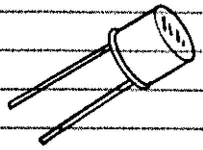
THE ZENER DIODE IS DESIGNED TO HAVE A SPECIFIC *REVERSE BREAKDOWN* (CONDUCTION) *VOLTAGE*. THIS MEANS ZENER DIODES CAN FUNCTION LIKE A VOLTAGE SENSITIVE SWITCH. ZENER DIODES HAVING BREAKDOWN VOLTAGES (V_z) OF FROM ABOUT 2-VOLTS TO 200-VOLTS ARE AVAILABLE.

LIGHT-EMITTING.



ALL DIODES EMIT SOME ELECTROMAGNETIC RADIATION WHEN FORWARD BIASED. DIODES MADE FROM CERTAIN SEMICONDUCTORS (LIKE GALLIUM ARSENIDE PHOSPHIDE) EMIT *CONSIDERABLY* MORE RADIATION THAN SILICON DIODES. THEY'RE CALLED LIGHT-EMITTING DIODES (LEDs).

PHOTODIODE.

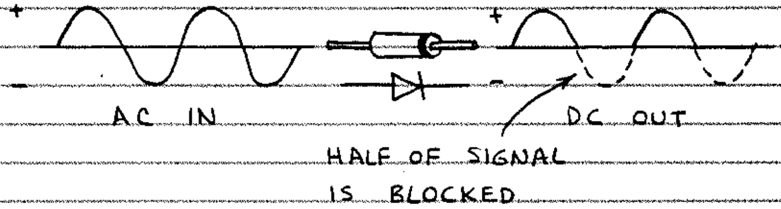


ALL DIODES RESPOND TO SOME DEGREE WHEN ILLUMINATED BY LIGHT. DIODES DESIGNED SPECIFICALLY TO DETECT LIGHT ARE CALLED PHOTODIODES. THEY INCLUDE A GLASS OR PLASTIC WINDOW THROUGH WHICH THE LIGHT ENTERS. OFTEN THEY HAVE A LARGE, EXPOSED JUNCTION REGION. SILICON MAKES GOOD PHOTODIODES.

HOW DIODES ARE USED

IN CHAPTER 9 YOU'LL SEE HOW VARIOUS TYPES OF DIODES ARE USED IN MANY APPLICATIONS. FOR NOW HERE ARE TWO OF THE MOST IMPORTANT ROLES FOR SMALL SIGNAL DIODES AND RECTIFIERS:

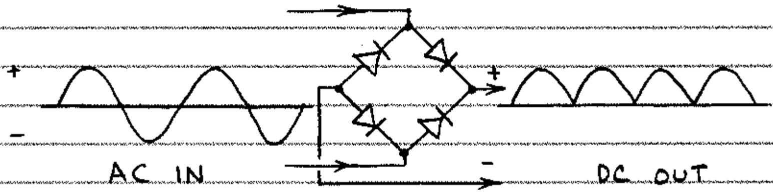
☐ HALF-WAVE RECTIFIER



AN UNDULATING (AC) SIGNAL (OR VOLTAGE) IS RECTIFIED INTO A SINGLE POLARITY (DC) SIGNAL (OR VOLTAGE).

☐ FULL-WAVE RECTIFIER

P. 101



THIS 4-DIODE "NETWORK" (OR BRIDGE RECTIFIER) RECTIFIES BOTH HALVES OF AN AC SIGNAL.

MORE ABOUT THE DIRECTION OF CURRENT FLOW

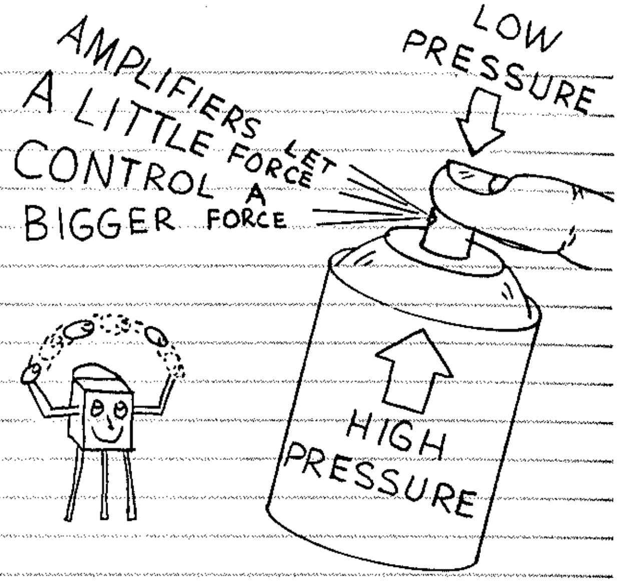
AN ELECTRICAL CURRENT IS THE MOVEMENT OF ELECTRONS THROUGH A CONDUCTOR OR SEMICONDUCTOR. SINCE ELECTRONS MOVE FROM A NEGATIVELY CHARGED TO A POSITIVELY CHARGED REGION, WHY DOES THE ARROWHEAD IN A DIODE SYMBOL POINT IN THE OPPOSITE DIRECTION? THERE ARE TWO REASONS:

1. BEGINNING WITH BENJAMIN FRANKLIN, IT WAS TRADITIONALLY ASSUMED ELECTRICITY FLOWS FROM A POSITIVELY CHARGED TO A NEGATIVELY CHARGED REGION. THE DISCOVERY OF THE ELECTRON CORRECTED THAT. (BUT MOST ELECTRICAL CIRCUIT DIAGRAMS TODAY STILL FOLLOW THE OLD TRADITION IN WHICH THE POSITIVE POWER SUPPLY CONNECTION IS PLACED ABOVE THE NEGATIVE CONNECTION AS IF GRAVITY SOMEHOW INFLUENCES THE FLOW OF A CURRENT.)

2. IN A SEMICONDUCTOR, AS SHOWN ON PAGE 44, HOLES FLOW IN THE DIRECTION OPPOSITE THAT OF ELECTRON FLOW. IT'S THEREFORE COMMON TO REFER TO POSITIVE CURRENT FLOW IN SEMICONDUCTORS.

FOR ACCURACY, IN THIS BOOK "CURRENT FLOW" REFERS TO ELECTRON FLOW. BUT WE'RE STUCK WITH SYMBOLS THAT INDICATE HOLE FLOW.

THE TRANSISTOR



AMPLIFIERS LET A LITTLE FORCE CONTROL A BIGGER FORCE
LOW PRESSURE
HIGH PRESSURE

TRANSISTORS ARE SEMICONDUCTOR DEVICES WITH THREE LEADS. A VERY SMALL CURRENT OR VOLTAGE AT ONE LEAD CAN CONTROL A MUCH LARGER CURRENT FLOWING THROUGH THE OTHER TWO LEADS. THIS MEANS TRANSISTORS CAN BE USED AS AMPLIFIERS AND SWITCHES. THERE ARE TWO MAIN FAMILIES OF TRANSISTORS: BIPOLAR AND FIELD-EFFECT.

BIPOLAR TRANSISTORS

ADD A SECOND JUNCTION TO A PN JUNCTION DIODE AND YOU GET A 3-LAYER SILICON SANDWICH. THE SANDWICH CAN BE EITHER NPN OR PNP. EITHER WAY, THE MIDDLE LAYER ACTS LIKE A FAUCET OR GATE THAT CONTROLS THE CURRENT MOVING THROUGH THE THREE LAYERS.

☐ BIPOLAR TRANSISTOR OPERATION — THE THREE LAYERS OF A BIPOLAR TRANSISTOR ARE THE EMITTER, BASE AND COLLECTOR. THE BASE IS VERY THIN AND HAS FEWER DOPING ATOMS THAN THE EMITTER AND COLLECTOR. THEREFORE A VERY SMALL EMITTER-BASE CURRENT WILL CAUSE A MUCH LARGER EMITTER-COLLECTOR CURRENT TO FLOW.

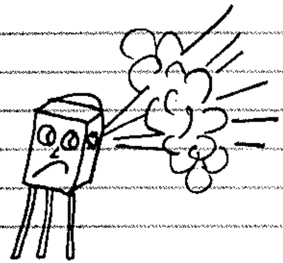
THE RESISTORS PROTECT THE TRANSISTOR FROM TOO MUCH CURRENT (WHICH CAN CAUSE EXCESSIVE HEAT).

☐ MORE ABOUT BIPOLAR TRANSISTOR OPERATION — DIODES AND TRANSISTORS SHARE SEVERAL KEY FEATURES:

1. THE BASE-EMITTER JUNCTION (OR DIODE) WILL NOT CONDUCT UNTIL THE FORWARD VOLTAGE EXCEEDS 0.6-VOLT.

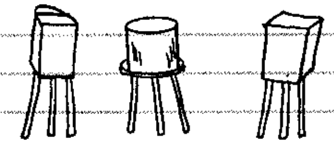
2. TOO MUCH CURRENT WILL CAUSE A TRANSISTOR TO BECOME HOT AND OPERATE IMPROPERLY. IF A TRANSISTOR IS HOT WHEN TOUCHED, DISCONNECT THE POWER TO IT!

3. TOO MUCH CURRENT OR VOLTAGE MAY DAMAGE OR PERMANENTLY DESTROY THE SEMICONDUCTOR CHIP THAT FORMS A TRANSISTOR. IF THE CHIP ISN'T HARMED, ITS TINY CONNECTION WIRES MAY MELT OR SEPARATE FROM THE CHIP. NEVER CONNECT A TRANSISTOR BACKWARDS!



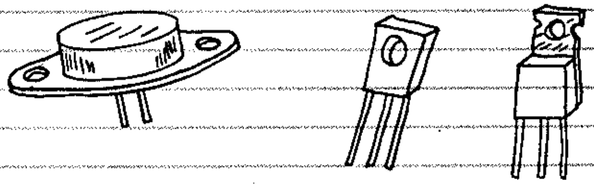
☐ KINDS OF TRANSISTORS — MANY DIFFERENT KINDS OF TRANSISTORS ARE AVAILABLE. HERE ARE EXAMPLES OF THE MOST IMPORTANT:

SMALL SIGNAL AND SWITCHING.



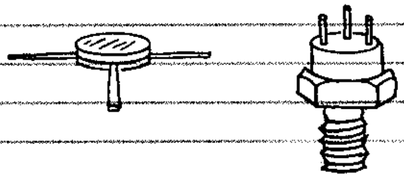
SMALL SIGNAL TRANSISTORS ARE USED TO AMPLIFY LOW LEVEL SIGNALS. SWITCHING TRANSISTORS ARE DESIGNED TO BE OPERATED FULLY ON OR OFF. SOME TRANSISTORS CAN BOTH AMPLIFY AND SWITCH EQUALLY WELL.

POWER.



POWER TRANSISTORS ARE USED IN HIGH POWER AMPLIFIERS AND POWER SUPPLIES. LARGE SIZE AND EXPOSED METAL SURFACES KEEP THEM COOL.

HIGH-FREQUENCY.



HIGH-FREQUENCY TRANSISTORS OPERATE AT RADIO, TELEVISION AND MICROWAVE FREQUENCIES. THE BASE REGION IS VERY THIN AND THE ACTUAL CHIP IS VERY SMALL.

HOW BIPOLAR TRANSISTORS ARE USED

WHEN THE BASE OF AN NPN TRANSISTOR IS GROUNDED (0 VOLTS), NO CURRENT FLOWS FROM THE EMITTER TO THE COLLECTOR (THE TRANSISTOR IS "OFF"). IF THE BASE IS FORWARD-BIASED BY AT LEAST 0.6 VOLT, A CURRENT WILL FLOW FROM THE EMITTER TO THE COLLECTOR (THE TRANSISTOR IS "ON"). WHEN OPERATED IN ONLY THESE TWO MODES, THE TRANSISTOR FUNCTIONS AS A SWITCH. IF THE BASE IS FORWARD-BIASED, THE EMITTER-COLLECTOR CURRENT WILL FOLLOW VARIATIONS IN A MUCH SMALLER BASE CURRENT. THE TRANSISTOR THEN FUNCTIONS AS AN AMPLIFIER. THIS DISCUSSION APPLIES TO A TRANSISTOR IN WHICH THE EMITTER IS THE GROUND CONNECTION FOR BOTH THE INPUT AND OUTPUT AND IS CALLED THE COMMON-EMITTER CIRCUIT. SOME SIMPLIFIED COMMON-EMITTER CIRCUITS ARE SHOWN BELOW. SO YOU CAN SEE HOW THEY ARE USED IN REAL CIRCUITS, EACH EXAMPLE REFERS TO A TYPICAL WORKING APPLICATION IN CHAPTER 9.

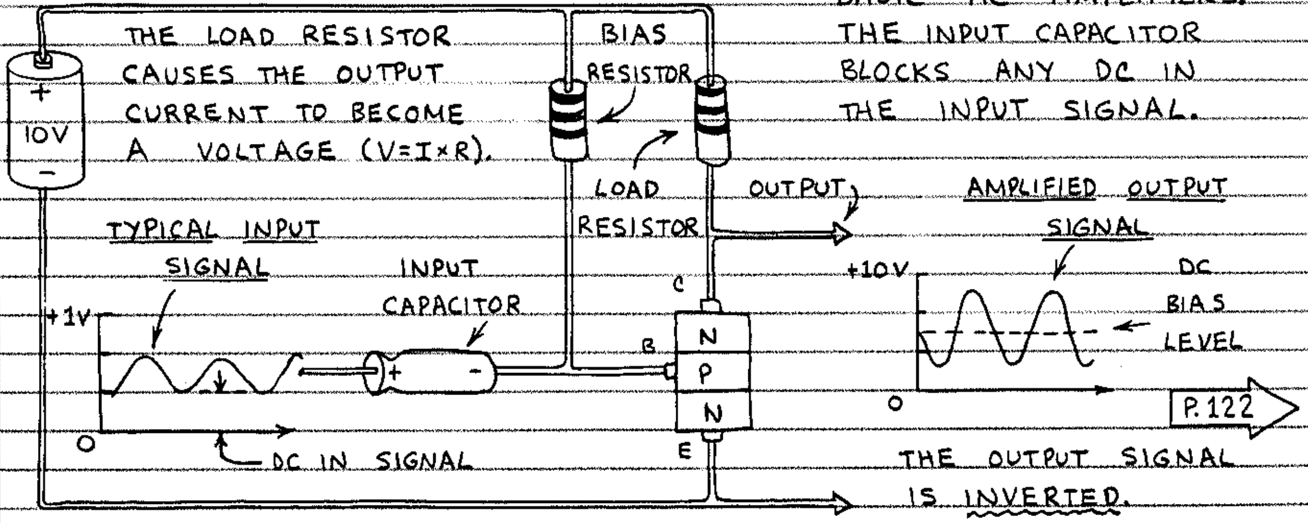
IN A WORKING CIRCUIT, THE VARIABLE RESISTOR MAY BE IN SERIES WITH A SECOND COMPONENT HAVING A RESISTANCE THAT VARIES WITH TEMPERATURE, LIGHT, MOISTURE, ETC. (WATER IS THE VARIABLE RESISTANCE IN THE MOISTURE METER ON P. 104.) WHEN THE INPUT SIGNAL CHANGES RAPIDLY, AN AC AMPLIFIER SUCH AS THE ONE BELOW IS USED.

☐ A BIPOLAR TRANSISTOR AC AMPLIFIER — THIS IS THE SIMPLEST OF SEVERAL BASIC AC AMPLIFIERS. THE INPUT CAPACITOR BLOCKS ANY DC IN THE INPUT SIGNAL.



THE LOAD RESISTOR CAUSES THE OUTPUT CURRENT TO BECOME A VOLTAGE (V=I×R).

THE OUTPUT SIGNAL IS INVERTED.

THE BIAS RESISTOR IS SELECTED TO GIVE AN OUTPUT VOLTAGE OF ABOUT HALF THE BATTERY VOLTAGE. THE AMPLIFIED SIGNAL "RIDES" ON THIS STEADY OUTPUT VOLTAGE AND VARIES ABOVE AND BELOW IT. (WITHOUT THE BIAS RESISTOR, ONLY THE POSITIVE HALF OF THE INPUT SIGNAL ABOVE 0.6 VOLT (SEE P. 45) WILL BE AMPLIFIED. THIS WILL CAUSE SEVERE DISTORTION.) TO SEE ONE WAY A WORKING VERSION OF THIS AMPLIFIER IS USED, TURN NOW TO P. 122 AND LOOK AT THE OUTPUT SECTION OF THE LIGHTWAVE TRANSMITTER.

FIELD-EFFECT TRANSISTORS

FIELD-EFFECT TRANSISTORS (OR FETs) HAVE BECOME MORE IMPORTANT THAN BIPOLAR TRANSISTORS. THEY ARE EASY TO MAKE AND REQUIRE LESS SILICON. THERE ARE TWO MAJOR FET FAMILIES, JUNCTION AND METAL-OXIDE-SEMICONDUCTOR. IN BOTH KINDS AN OUTPUT CURRENT IS CONTROLLED BY A SMALL INPUT VOLTAGE AND PRACTICALLY NO INPUT CURRENT!

JUNCTION FETs

THE TWO MAIN KINDS OF FETs ARE N-CHANNEL AND P-CHANNEL. THE CHANNEL IS LIKE A SILICON RESISTOR THAT CONDUCTS CURRENT MOVING FROM THE SOURCE TO THE DRAIN. A VOLTAGE AT THE GATE INCREASES THE CHANNEL RESISTANCE AND REDUCES THE DRAIN-SOURCE CURRENT. THEREFORE THE FET CAN BE USED AS AN AMPLIFIER OR A SWITCH.

☐ JUNCTION FET OPERATION— THE ARRANGEMENT BELOW SHOWS HOW AN N-CHANNEL FET WORKS. A NEGATIVE GATE VOLTAGE CREATES TWO HIGH RESISTANCE REGIONS (THE FIELD) IN THE CHANNEL ADJACENT TO THE P-TYPE SILICON. MORE GATE VOLTAGE WILL CAUSE THE FIELDS TO MERGE TOGETHER AND COMPLETELY BLOCK THE CURRENT. THE GATE-CHANNEL RESISTANCE IS VERY HIGH.

☐ MORE ABOUT JUNCTION FETs — SINCE THEY ARE VOLTAGE CONTROLLED, JUNCTION FETs (OR JFETs) HAVE IMPORTANT ADVANTAGES OVER CURRENT-CONTROLLED BIPOLAR TRANSISTORS:

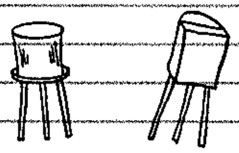
1. THE GATE-CHANNEL RESISTANCE OF A JFET IS VERY HIGH (MILLIONS OF OHMS). THEREFORE THE JFET HAS LITTLE OR NO EFFECT ON EXTERNAL COMPONENTS OR CIRCUITS CONNECTED TO ITS GATE.

2. THE VERY HIGH GATE-CHANNEL RESISTANCE MEANS PRACTICALLY NO CURRENT FLOWS IN THE GATE CIRCUIT. (WHY IS THE RESISTANCE SO HIGH? THE GATE AND CHANNEL FORM A DIODE. SO LONG AS THE INPUT SIGNAL REVERSE BIASES THIS DIODE, THE GATE HAS VERY HIGH INPUT RESISTANCE.)

3. LIKE BIPOLAR TRANSISTORS, JFETs CAN BE DAMAGED OR DESTROYED BY EXCESSIVE CURRENT OR VOLTAGE.

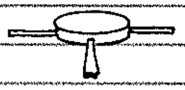
☐ KINDS OF JUNCTION FETs — JFETs ARE USED IN MANY DIFFERENT APPLICATIONS. SINCE THEY CANNOT BE USED FOR HIGH POWER ROLES, MOST ARE INSTALLED IN SMALL PLASTIC OR METAL PACKAGES. HERE ARE THE MAIN CATEGORIES:

SMALL SIGNAL AND SWITCHING.



SMALL SIGNAL JFETs ARE USED AT THE INPUT STAGE OF AMPLIFIERS TO PROVIDE A HIGH RESISTANCE INPUT. THEY ARE ALSO USED AS SWITCHES.

HIGH FREQUENCY.



HIGH FREQUENCY JFETS ARE USED TO AMPLIFY OR PRODUCE HIGH FREQUENCY SIGNALS.

☐ JUNCTION FET SYMBOLS — GATES INTERNALLY CONNECTED.

P-CHANNEL

METAL-OXIDE-SEMICONDUCTOR FETs

THE METAL-OXIDE-SEMICONDUCTOR FET (OR MOSFET) HAS BECOME THE MOST IMPORTANT TRANSISTOR. MOST MICROCOMPUTER AND MEMORY INTEGRATED CIRCUITS ARE ARRAYS OF THOUSANDS OF MOSFETs ON A SMALL SLIVER OF SILICON. WHY? MOSFETs ARE EASY TO MAKE, THEY CAN BE VERY SMALL, AND SOME MOSFET CIRCUITS CONSUME NEGLIGIBLE POWER. NEW KINDS OF POWER MOSFETs ARE ALSO VERY USEFUL.

☐ MOSFET OPERATION— ALL MOSFETs ARE N-TYPE OR P-TYPE. UNLIKE THE JUNCTION FET, THE GATE OF A MOSFET HAS NO ELECTRICAL CONTACT WITH THE SOURCE AND DRAIN. A GLASS-LIKE LAYER OF SILICON-DIOXIDE (AN INSULATOR) SEPARATES THE GATE'S METAL CONTACT FROM THE REST OF THE TRANSISTOR.

A POSITIVE GATE VOLTAGE ATTRACTS ELECTRONS TO THE REGION BELOW THE GATE. THIS CREATES A THIN N-TYPE CHANNEL IN THE P-TYPE SILICON BETWEEN THE SOURCE AND DRAIN. CURRENT CAN THEN FLOW THROUGH THE CHANNEL. THE GATE VOLTAGE DETERMINES THE RESISTANCE OF THE CHANNEL.

☐ MORE ABOUT MOSFETs — THE INPUT RESISTANCE OF THE MOSFET IS THE HIGHEST OF ANY TRANSISTOR. THIS AND OTHER FACTORS GIVE MOSFETs IMPORTANT ADVANTAGES:

1. THE GATE-CHANNEL RESISTANCE IS ALMOST INFINITE (TYPICALLY 1,000,000,000,000,000-OHMS). THIS MEANS THE GATE PULLS NO CURRENT FROM EXTERNAL CIRCUITS. (WELL, IT MAY BORROW A FEW TRILLIONTHS OF AN AMPERE.)

2. MOSFETs CAN FUNCTION AS VOLTAGE-CONTROLLED VARIABLE RESISTORS. THE GATE VOLTAGE CONTROLS CHANNEL RESISTANCE.

3. NEW KINDS OF MOSFETs CAN SWITCH VERY HIGH CURRENTS IN A FEW BILLIONTHS OF A SECOND.

☐ CAUTION — BECAUSE THE GLASS-LIKE SILICON OXIDE LAYER BELOW THE GATE IS SO THIN, IT CAN BE PIERCED BY TOO MUCH VOLTAGE OR EVEN STATIC ELECTRICITY. EVEN THE STATIC CHARGE GENERATED BY CLOTHING OR A CELLOPHANE WRAPPER CAN ZAP THE GATE OF A MOSFET!

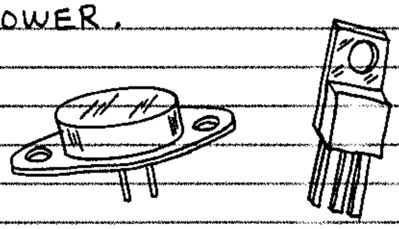
☐ KINDS OF MOSFETs — LIKE JFETs, MOSFETs INSTALLED IN SMALL METAL OR PLASTIC PACKAGES ARE USED TO GIVE AMPLIFIERS AN ULTRA-HIGH INPUT RESISTANCE. THEY ARE ALSO USED AS VOLTAGE CONTROLLED RESISTORS AND SWITCHES. THE MOST IMPORTANT CATEGORY HAS BECOME:

POWER.



POWER MOSFETs ALLOW A FEW VOLTS TO SWITCH OR AMPLIFY MANY AMPERES AT VERY FAST SPEEDS.

HOW FETs ARE USED

FIELD-EFFECT TRANSISTORS ARE USED AS AMPLIFIERS, SWITCHES AND VOLTAGE-CONTROLLED RESISTORS. HERE ARE SOME TYPICAL CIRCUIT ARRANGEMENTS.

☐ A JFET ELECTROMETER — THIS ULTRA-SIMPLE CIRCUIT IS THE ELECTRONIC VERSION OF THE ELECTROSCOPE. THE GATE LEAD OF AN N-CHANNEL JFET IS LEFT DISCONNECTED. NORMALLY A CURRENT FLOWS FROM SOURCE TO DRAIN. WHEN A NEGATIVELY CHARGED OBJECT (LIKE A PLASTIC COMB THAT'S BEEN STROKED THROUGH YOUR HAIR) IS PLACED NEAR THE GATE, THE CURRENT FLOW IS REDUCED OR STOPPED.

THE UNIJUNCTION TRANSISTOR (UJT) IS NOT A TRUE TRANSISTOR. IT'S MORE LIKE A DIODE WITH TWO CATHODE CONNECTIONS. IT WORKS LIKE A VOLTAGE-CONTROLLED SWITCH AND DOES NOT AMPLIFY.

☐ UJT OPERATION —

NORMALLY A SMALL CURRENT WILL FLOW FROM BASE 1 TO BASE 2. WHEN THE VOLTAGE APPLIED TO THE EMITTER REACHES A CERTAIN THRESHOLD (SEVERAL VOLTS), THE UJT SWITCHES ON AND A HIGH CURRENT FLOWS FROM BASE 1 TO THE EMITTER. BELOW THE THRESHOLD VOLTAGE, NO CURRENT FLOWS FROM BASE 1 TO THE EMITTER.

THE THYRISTOR

THYRISTORS ARE SEMICONDUCTOR DEVICES WITH THREE LEADS. A SMALL CURRENT AT ONE LEAD WILL ALLOW A MUCH LARGER CURRENT TO FLOW THROUGH THE OTHER TWO LEADS. THE CONTROLLED CURRENT IS EITHER ON OR OFF. THEREFORE THYRISTORS DO NOT AMPLIFY FLUCTUATING SIGNALS LIKE TRANSISTORS DO. INSTEAD THEY ARE SOLID-STATE SWITCHES. THERE ARE TWO FAMILIES OF THYRISTORS, SILICON-CONTROLLED RECTIFIERS (SCRs) AND TRIACs. SCRs SWITCH DIRECT CURRENT AND TRIACs SWITCH ALTERNATING CURRENT.

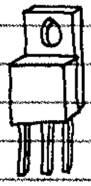
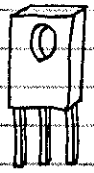
MEDIUM CURRENT.





THESE SCRs SWITCH UP TO 10-AMPERES AT UP TO SEVERAL HUNDRED VOLTS. ONE COMMON USE IS SOLID-STATE SWITCHING FOR AUTO ENGINES.

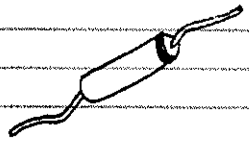
TWO-LEAD THYRISTORS

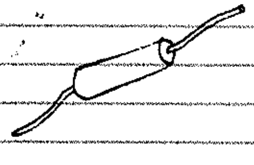
AN SCR OR TRIAC WILL SWITCH ON WITHOUT A GATE SIGNAL IF THE VOLTAGE ACROSS ITS OTHER TWO LEADS REACHES A CERTAIN LEVEL (THE BREAKDOWN VOLTAGE). THIS SELF-SWITCHING ABILITY MAKES POSSIBLE TWO-LEAD THYRISTORS.

FOUR-LAYER DIODE.



A FOUR-LAYER DIODE IS AN SCR WITHOUT A GATE. IT SWITCHES DC VOLTAGE.

DIAC.



A DIAC IS A THREE-LAYER DEVICE SIMILAR TO A PNP JUNCTION TRANSISTOR WITHOUT A BASE LEAD. IT SWITCHES AC VOLTAGE.

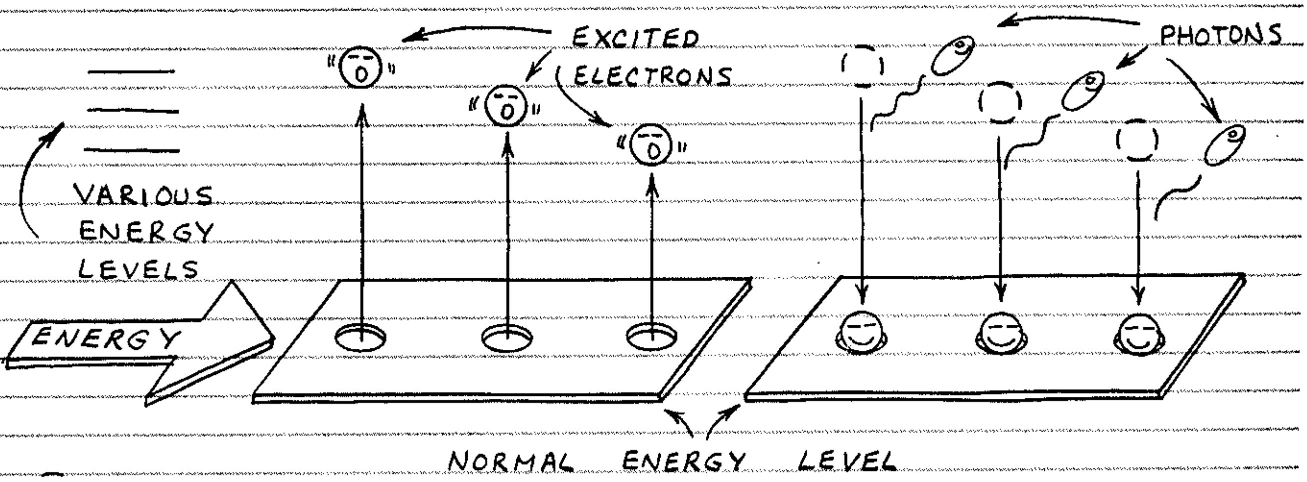
4. PHOTONIC SEMICONDUCTORS

PHOTONICS IS THE FAST GROWING FIELD OF ELECTRONICS INVOLVING SEMICONDUCTOR DEVICES THAT EMIT AND DETECT LIGHT. BEFORE LOOKING AT SOME PHOTONIC COMPONENTS, LET'S TAKE A QUICK LOOK AT SOME FACTS ABOUT LIGHT.

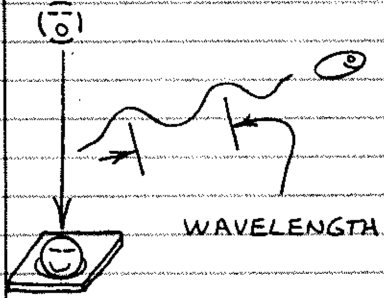
LIGHT

"LET THERE BE LIGHT..."

LIGHT IS COMPOSED OF PARTICLES CALLED PHOTONS THAT BEHAVE LIKE WAVES OF ENERGY. PHOTONS ARE NOT NECESSARILY VISIBLE AND ONLY THOSE YOU CAN SEE ARE COLLECTIVELY CALLED LIGHT. PHOTONS ARE PRODUCED WHEN AN ELECTRON THAT'S BEEN EXCITED TO A HIGHER THAN NORMAL ENERGY LEVEL FALLS BACK TO ITS NORMAL LEVEL.

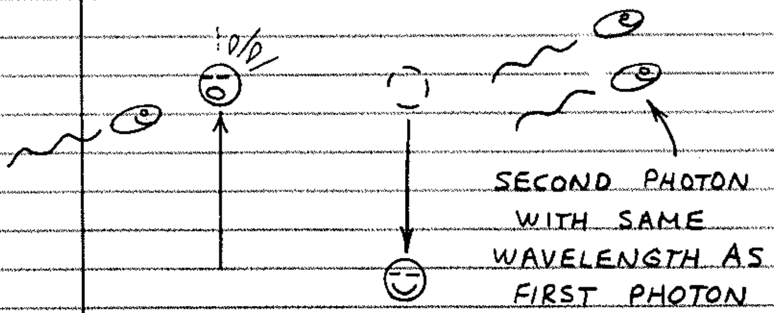


EXCITED ELECTRONS
PHOTONS
VARIOUS ENERGY LEVELS
ENERGY
NORMAL ENERGY LEVEL



WAVELENGTH

REMEMBER, PHOTONS ACT LIKE WAVES. THE DISTANCE BETWEEN CRESTS IS THE WAVELENGTH. ELECTRONS EXCITED TO HIGHER ENERGY LEVELS EMIT PHOTONS WITH SHORTER WAVELENGTHS THAN ELECTRONS EXCITED TO LOWER LEVELS.



SECOND PHOTON WITH SAME WAVELENGTH AS FIRST PHOTON

EXCITED ELECTRONS CAN RESUME THEIR NORMAL LEVEL SPONTANEOUSLY. OR A PHOTON WITH THE PROPER WAVELENGTH CAN STIMULATE AN EXCITED ELECTRON TO RETURN TO ITS NORMAL LEVEL.

☐ THE ELECTROMAGNETIC SPECTRUM — VISIBLE LIGHT IS A FORM OF ELECTROMAGNETIC RADIATION. THE WAVELENGTH OF LIGHT IS SPECIFIED IN NANOMETERS (1-NANOMETER IS A BILLIONTH OF A METER). THE DIAGRAM BELOW SHOWS THE RELATIONSHIP OF LIGHT TO OTHER FORMS OF ELECTROMAGNETIC RADIATION.

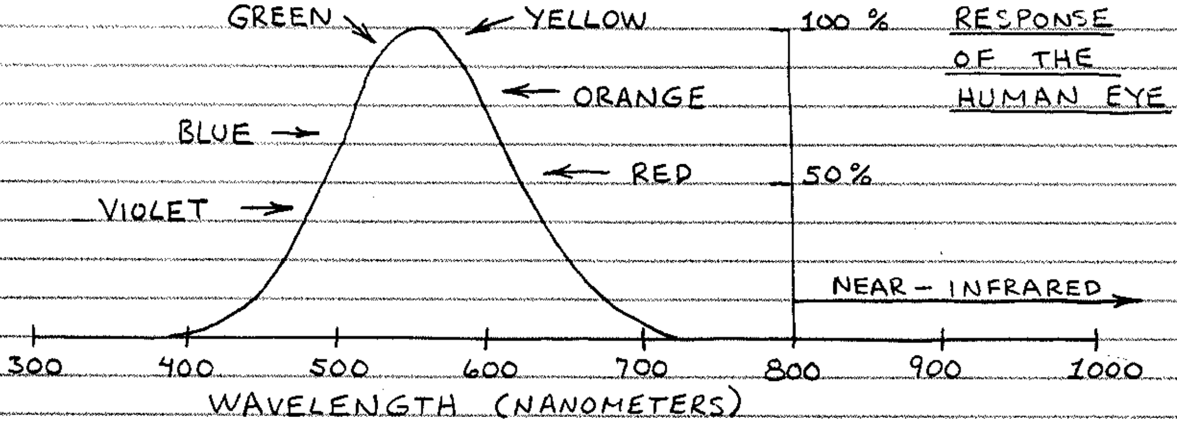
☐ THE OPTICAL SPECTRUM — ULTRAVIOLET, VISIBLE AND INFRARED RADIATION ARE TOGETHER CALLED THE *OPTICAL SPECTRUM*. HERE'S AN EXPANDED DIAGRAM OF THE OPTICAL SPECTRUM:

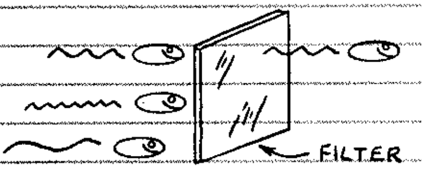


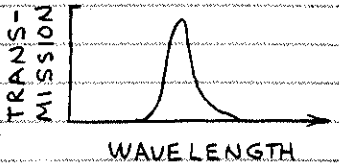
MANY PHOTONIC SEMICONDUCTORS EMIT OR DETECT *NEAR-INFRARED* RADIATION. SILICON, FOR EXAMPLE, CAN DETECT VISIBLE LIGHT. BUT IT IS MOST SENSITIVE TO NEAR-INFRARED AT ABOUT 880 nm. BECAUSE SO MANY PHOTONIC COMPONENTS CAN OPERATE IN BOTH THE VISIBLE AND NEAR-INFRARED, IT'S COMMON TO REFER TO NEAR-INFRARED AS LIGHT.

OPTICAL COMPONENTS

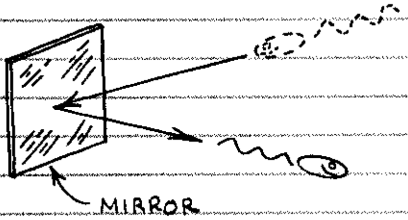
OPTICAL COMPONENTS CONDUCT, BEND OR CHANGE THE CHARACTERISTICS OF LIGHT. SEVERAL ARE VERY IMPORTANT IN MANY APPLICATIONS OF PHOTONIC SEMICONDUCTORS:

1. FILTERS TRANSMIT ONLY A NARROW BAND OF OPTICAL WAVELENGTHS.



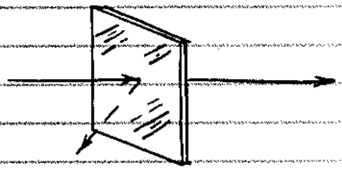


2. REFLECTORS REFLECT SOME OR MOST OF AN ONCOMING LIGHT BEAM. SOME LIGHT MAY OR MAY NOT BE TRANSMITTED.



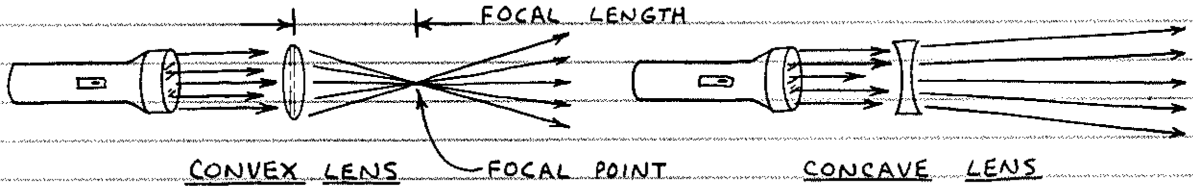
THOSE WITH A VERY SMOOTH SURFACE (LIKE MIRRORS) ARE CALLED SPECULAR REFLECTORS.

3. BEAMSPLITTERS REFLECT PART OF AN ONCOMING LIGHT BEAM AND TRANSMIT THE REMAINDER.



A GLASS MICROSCOPE SLIDE MAKES A GOOD BEAM SPLITTER. (EACH SURFACE REFLECTS 4%.)

4. LENSES BEND LIGHT. THE MOST IMPORTANT ARE:

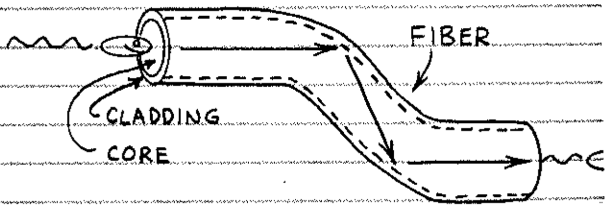


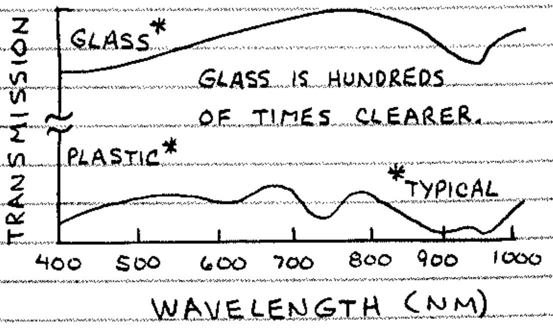
CONVEX LENS

CONCAVE LENS

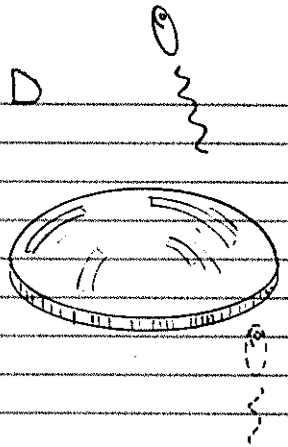
CONVEX LENSES ARE OFTEN USED IN CONJUNCTION WITH SEMICONDUCTOR LIGHT SOURCES AND DETECTORS. FOR EXAMPLE, THEY CAN COLLECT AND FOCUS LIGHT ONTO A MINIATURE DETECTOR.

5. OPTICAL FIBERS ARE THIN, FLEXIBLE STRANDS OF HIGHLY TRANSPARENT GLASS OR PLASTIC THAT CONDUCT LIGHT. THE LIGHT TRAVELS THROUGH A CORE SURROUNDED BY A THIN CLADDING. PLASTIC FIBERS ARE INEXPENSIVE. GLASS FIBERS ARE MUCH MORE TRANSPARENT. BOTH KINDS TRANSMIT SOME WAVELENGTHS MUCH BETTER THAN OTHERS. HIGH QUALITY FIBERS ARE USED TO SEND TELEPHONE CALLS AND COMPUTER DATA VIA PULSES OF LIGHT.





HOW CONVEX LENSES ARE USED



MANY SEMICONDUCTOR LIGHT SOURCES AND DETECTORS ARE EQUIPPED WITH A BUILT-IN CONVEX LENS. THIS PAGE EXPLAINS WHY AND SHOWS HOW EXTERNAL LENS ARE USED WITH SOURCES AND DETECTORS.

FAMOUS FACT: LIGHT TRAVELS 186,291 MILES PER SECOND!

AS LIGHT FROM A VERY SMALL SOURCE SPREADS OUTWARD, ITS INTENSITY IS INVERSELY PROPORTIONAL TO THE SQUARE OF THE DISTANCE. IN OTHER WORDS, IF THE DISTANCE IS 3, THEN THE INTENSITY IS 1/9 THE INTENSITY WHEN THE DISTANCE IS 1. A CONVEX LENS CAN CANCEL THIS INTENSITY REDUCTION.

SEMICONDUCTOR LIGHT SOURCES

WHEN BOMBARDED BY LIGHT, HEAT, ELECTRONS AND OTHER FORMS OF ENERGY, MOST SEMICONDUCTOR CRYSTALS WILL EMIT VISIBLE OR INFRARED LIGHT. THE BEST SEMICONDUCTOR LIGHT SOURCES, HOWEVER, ARE PN JUNCTION DIODES.

☐ LED OPERATION— THE FORWARD VOLTAGE ACROSS A DIODE MUST EXCEED A THRESHOLD LEVEL BEFORE A CURRENT CAN CROSS THE JUNCTION. FOR SILICON, WHICH EMITS A TINY AMOUNT OF NEAR-INFRARED, THE THRESHOLD IS 0.6-VOLT. FOR GALLIUM ARSENIDE, WHICH EMITS CONSIDERABLE NEAR-INFRARED, THE THRESHOLD IS 1.3-VOLTS. THIS VOLTAGE EXCITES THE ELECTRONS. WHEN THE ELECTRONS CROSS THE JUNCTION AND COMBINE WITH HOLES, THEY EMIT PHOTONS.

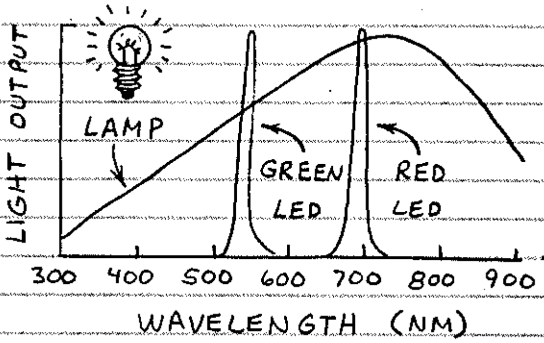
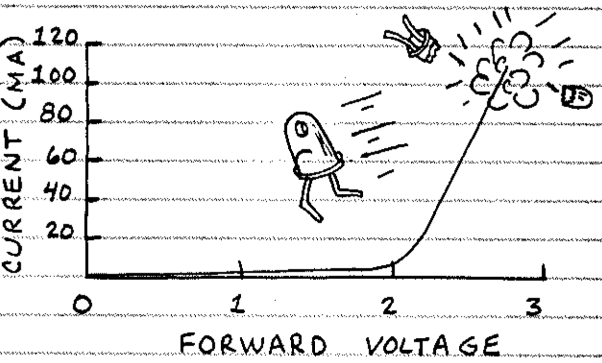
☐ MORE ABOUT LED OPERATION — HERE ARE SOME KEY ASPECTS OF LED OPERATION YOU SHOULD KNOW ABOUT:

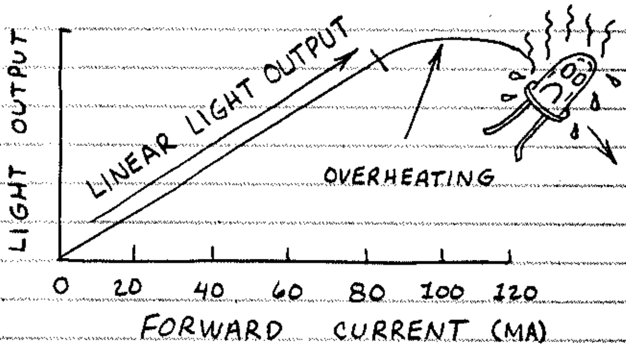
1. THE LIGHT EMITTED BY AN INCANDESCENT LAMP CONTAINS MANY WAVELENGTHS. THE LIGHT EMITTED BY AN LED HAS A NARROW WAVELENGTH RANGE. (THIS IS BECAUSE THE ELECTRONS IN THE LED ARE ALL EXCITED TO THE SAME LEVEL.)



2. WHEN AN LED BEGINS TO CONDUCT, THE VOLTAGE INCREASES GRADUALLY WHILE THE CURRENT INCREASES RAPIDLY. TOO MUCH CURRENT WILL OVERHEAT THE LED AND POSSIBLY SEPARATE THE LEADS OR MELT THE SEMICONDUCTOR CHIP.



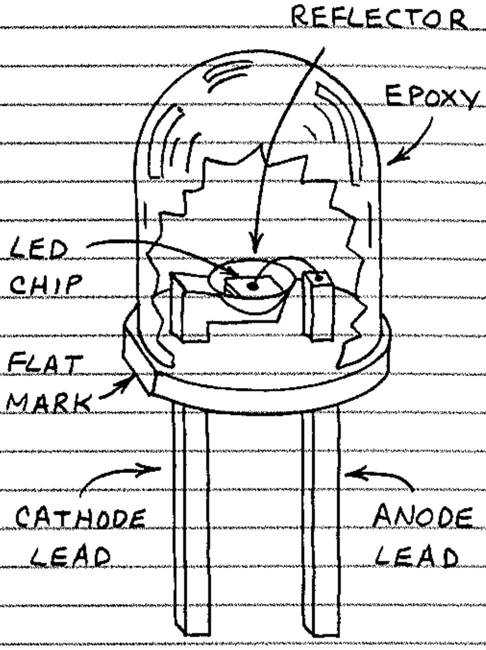
3. THE LIGHT EMITTED BY AN LED IS DIRECTLY PROPORTIONAL TO CURRENT THROUGH THE LED. THIS MEANS LEDS ARE IDEAL FOR TRANSMITTING INFORMATION. THE LIGHT OUTPUT FROM AN OVERHEATED LED WILL SOON DECREASE. THE LED MAY EVEN BE DAMAGED.



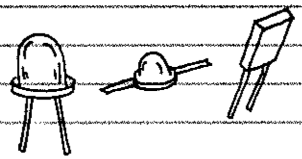
4. THE FORWARD VOLTAGE AND WAVELENGTH OF AN LED ARE DIRECTLY RELATED. THEREFORE IT'S NOT ALWAYS POSSIBLE TO SUBSTITUTE DIFFERENT LEDS WITHOUT CHANGING THE VOLTAGE AND CURRENT. MANY DIFFERENT SEMICONDUCTORS ARE USED TO MAKE VARIOUS LEDS. VISIBLE LIGHT EMITTING LEDs EMIT UP TO A MILLIWATT OR SO OF POWER. SOME INFRARED LEDs (LIKE 880 NM UNITS) EMIT 15 OR MORE MILLIWATTS! (A FLASHLIGHT EMITS 10 OR MORE MILLIWATTS.)

WAVELENGTH (NM)	VOLTAGE
565 (GREEN)	2.2 — 3.0
590 (YELLOW)	2.2 - 3.0
615 (ORANGE)	1.8 - 2.7
640 (RED)	1.6 - 2.0
690 (RED)	2.2 - 3.0
880 (INFRARED)	2.0 - 2.5
900 (INFRARED)	1.2 - 1.6
940 (INFRARED)	1.3 - 1.7

☐ KINDS OF LEDs — SINCE THE LED IS A LIGHT SOURCE, IT'S HELPFUL TO KNOW WHAT'S INSIDE THE PLASTIC OR METAL LED CASE. SHOWN HERE IS A TYPICAL LED. THE HEAVY LEADS HELP CONDUCT HEAT AWAY FROM THE CHIP. THE REFLECTOR COLLECTS LIGHT EMITTED FROM THE EDGES OF THE CHIP. THE EPOXY IS USUALLY COLORED WHEN THE LED IS A VISIBLE LIGHT EMITTER. LIGHT SCATTERING PARTICLES ARE OFTEN ADDED TO THE EPOXY. THIS DIFFUSES THE LIGHT AND CAUSES THE END OF THE LED TO APPEAR BRIGHTER.

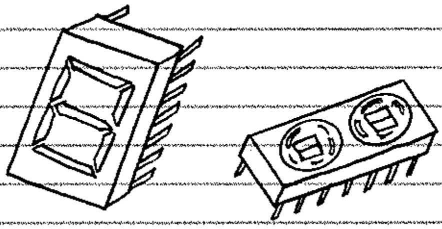


VISIBLE LIGHT LEDs.



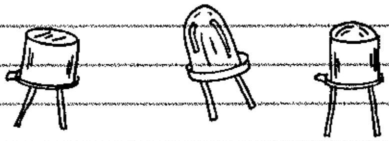
THESE INEXPENSIVE LEDs ARE USED AS INDICATOR LIGHTS. CERTAIN RED LEDs ARE USED TO TRANSMIT INFORMATION. MOST ARE ENCAPSULATED IN EPOXY.

LED DISPLAYS.



MANY KINDS OF LED READOUTS CAPABLE OF DISPLAYING DIGITS AND CHARACTERS ARE AVAILABLE. THEY ARE MORE RUGGED THAN LIQUID CRYSTAL DISPLAYS, BUT THEY USE MUCH MORE CURRENT.

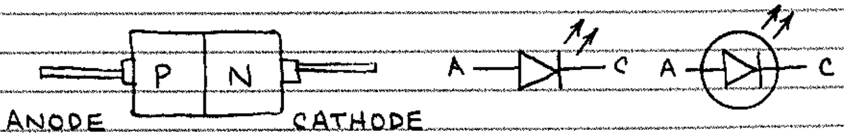
INFRARED LEDs.



INFRARED LEDs SHOULD BE CALLED INFRARED EMITTING DIODES. THEY ARE USED TO TRANSMIT INFORMATION. THEY ARE ALSO USED IN INTRUSION ALARMS, REMOTE CONTROL DEVICES, ETC. A SPECIAL KIND OF INFRARED LED IS THE DIODE LASER. SOME EMIT SEVERAL WATTS!

☐ LED SYMBOL.

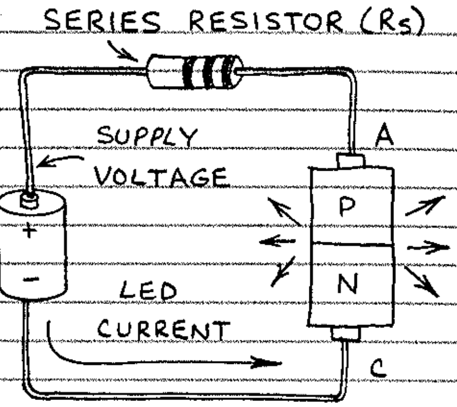
BOTH SYMBOLS SHOWN HERE ARE USED.



HOW LEDs ARE USED

LEDs CAN BE POWERED BY CONTINUOUS CURRENT OR BY BRIEF PULSES OF CURRENT. WHEN OPERATED CONTINUOUSLY, THE CURRENT CAN BE VARIED TO CHANGE THE LIGHT OUTPUT.

☐ LED DRIVE CIRCUIT — BECAUSE LEDs ARE CURRENT DEPENDENT, IT'S USUALLY NECESSARY TO PROTECT THEM FROM EXCESSIVE CURRENT WITH A SERIES RESISTOR. SOME LEDs INCLUDE A BUILT-IN SERIES RESISTOR. MOST DO NOT. IT'S IMPORTANT TO KNOW HOW TO DETERMINE THE REQUIRED SERIES RESISTANCE (R_S). THE FORMULA IS:

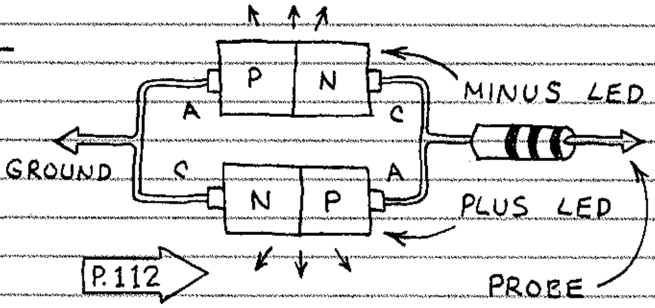


$$R_S = \frac{\text{SUPPLY VOLTAGE} - \text{LED VOLTAGE}}{\text{LED CURRENT}} \quad \text{OR} \quad R_S = \frac{V - V_{LED}}{I_{LED}}$$

P.112

EXAMPLE: SUPPOSE YOU WANT TO OPERATE A RED LED AT A FORWARD CURRENT (I_{LED}) OF 10-MILLIAMPERES FROM A 5-VOLT SUPPLY (V). V_{LED} IS 1.7-VOLTS (FROM DATA SHEET). THEREFORE R_S IS $(5-1.7)/0.01$ OR 330-OHMS.

☐ LED POLARITY INDICATOR — TWO REVERSE-PARALLEL LEDs FORM A POLARITY INDICATOR. BOTH LEDs GLOW IF THE TESTED VOLTAGE IS AC. THE SERIES RESISTOR MUST BE USED!



P.112

☐ PULSED LED — WHEN OPERATED CONTINUOUSLY, AN INFRARED LED MIGHT HAVE A MAXIMUM CURRENT OF 100-MILLIAMPERES. WHEN DRIVEN BY BRIEF PULSES OF CURRENT, THE SAME LED MAY SAFELY ACCEPT HUGE 10-AMPERE PULSES!

NOTE:
A SERIES RESISTOR MAY NOT BE REQUIRED IF THE PULSES DO NOT EXCEED THE MAXIMUM LEVELS SPECIFIED FOR THE LED.

PHOTON

ENERGY ENTERING A SEMICONDUCTOR CRYSTAL EXCITES ELECTRONS TO HIGHER LEVELS, LEAVING BEHIND HOLES. THESE ELECTRONS AND HOLES CAN RECOMBINE AND EMIT PHOTONS, OR THEY CAN MOVE AWAY FROM ONE ANOTHER AND FORM A CURRENT. THIS IS THE BASIS OF SEMICONDUCTOR LIGHT DETECTORS. THERE ARE TWO MAJOR CLASSES OF SEMICONDUCTOR LIGHT DETECTORS, THOSE WITH AND THOSE WITHOUT PN JUNCTIONS.

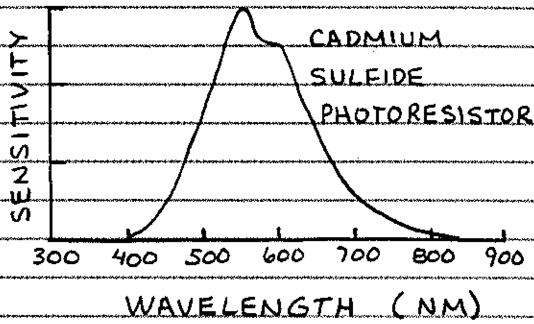
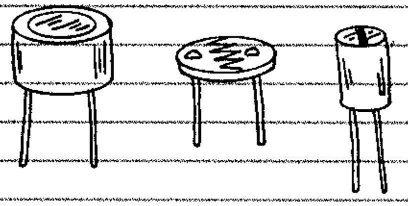
☐ MORE ABOUT PHOTORESISTOR OPERATION — HERE ARE SOME IMPORTANT ASPECTS OF PHOTORESISTOR OPERATION:

1. PHOTORESISTORS MAY REQUIRE A FEW MILLISECONDS OR MORE TO FULLY RESPOND TO A CHANGE IN LIGHT INTENSITY (THAT'S PRETTY SLOW). THEY MAY REQUIRE MANY MINUTES TO RETURN TO THEIR NORMAL DARK RESISTANCE WHEN LIGHT IS REMOVED (THE MEMORY EFFECT).

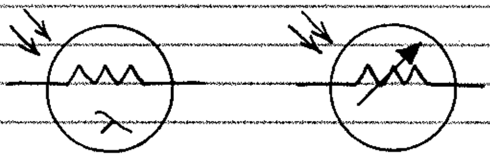
2. THE SEMICONDUCTOR MOST OFTEN USED IN PHOTORESISTORS IS CADMIUM SULFIDE. ITS SENSITIVITY TO LIGHT IS VERY SIMILAR TO THAT OF THE HUMAN EYE! LEAD SULFIDE IS USED TO DETECT INFRARED (OUT TO 3-MICROMETERS).



☐ KINDS OF PHOTORESISTORS — MANY DIFFERENT KINDS ARE AVAILABLE. IN MOST THE LIGHT SENSITIVE SEMICONDUCTOR IS COATED BETWEEN INTERLEAVED ELECTRODES TO INCREASE THE EXPOSED SURFACE. A PLASTIC OR GLASS WINDOW MAY OR MAY NOT BE USED.



☐ PHOTORESISTOR SYMBOL. BOTH SYMBOLS SHOWN HERE ARE USED.

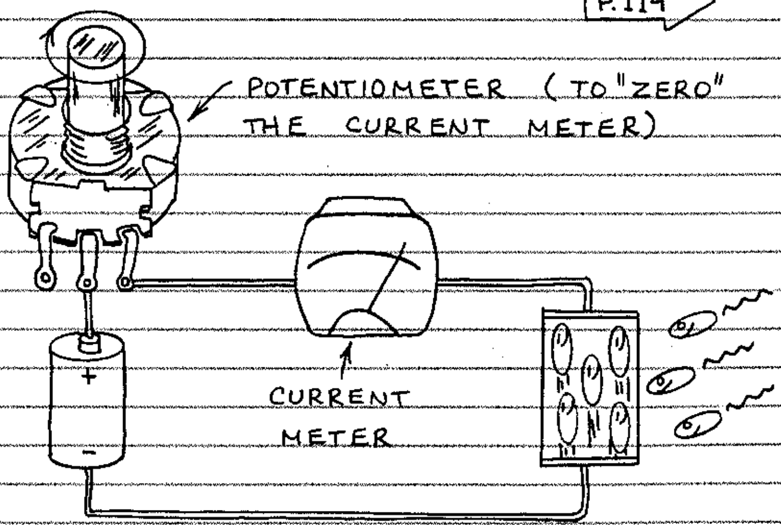


HOW PHOTORESISTORS ARE USED

P. 114

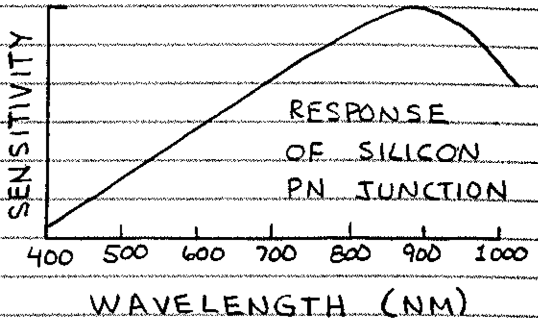
PHOTORESISTORS ARE USED IN LIGHT CONTROLLED RELAYS AND LIGHT METERS.

☐ LIGHT METER. THE ARRANGEMENT SHOWN HERE INDICATES ON A CURRENT METER THE INTENSITY OF LIGHT ILLUMINATING A CADMIUM SULFIDE PHOTORESISTOR.



PN JUNCTION LIGHT DETECTORS

PN JUNCTION LIGHT DETECTORS FORM THE LARGEST FAMILY OF PHOTONIC SEMICONDUCTORS. MOST ARE MADE FROM SILICON AND CAN DETECT BOTH VISIBLE LIGHT AND NEAR-INFRARED.



PHOTODIODES

ALL PN JUNCTIONS ARE LIGHT SENSITIVE. PHOTODIODES ARE PN JUNCTIONS SPECIFICALLY DESIGNED FOR LIGHT DETECTION. THEY ARE USED IN CAMERAS, INTRUSION ALARMS, LIGHTWAVE COMMUNICATORS, ETC.

ALL TRANSISTORS ARE LIGHT SENSITIVE. PHOTOTRANSISTORS ARE SPECIFICALLY DESIGNED TO TAKE ADVANTAGE OF THIS IMPORTANT PROPERTY. LIGHT SENSITIVE FETs ARE AVAILABLE, BUT THE MOST COMMON PHOTO-TRANSISTOR IS AN NPN JUNCTION TRANSISTOR WITH A LARGE, EXPOSED BASE REGION. PHOTONS ENTERING THE BASE REPLACE THE BASE-EMITTER CURRENT OF ORDINARY NPN TRANSISTORS. THEREFORE A PHOTOTRANSISTOR DIRECTLY AMPLIFIES VARIATIONS IN THE NUMBER OF PHOTONS.

PHOTOTHYRISTORS

PHOTOTHYRISTORS ARE VARIOUS KINDS OF LIGHT-ACTIVATED THYRISTORS. YOU CAN THINK OF THEM AS LIGHT-ACTIVATED SWITCHES. THE MOST IMPORTANT MEMBER OF THE FAMILY IS THE LIGHT-ACTIVATED SILICON CONTROLLED RECTIFIER (LASCR). LIGHT ACTIVATED TRIACS ARE ALSO MADE. NEITHER CAN SWITCH AS MUCH CURRENT AS CONVENTIONAL THYRISTORS.

TO IMPROVE THEIR SENSITIVITY TO LIGHT, THE LASCR IS MADE THINNER THAN STANDARD SCRs. THIS LIMITS THE AMOUNT OF CURRENT THEY CAN SWITCH. FOR HIGH CURRENT APPLICATIONS A LASCR CAN BE USED TO TRIGGER A CONVENTIONAL SCR.

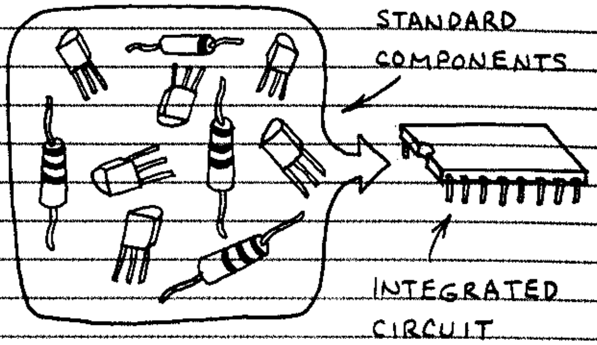
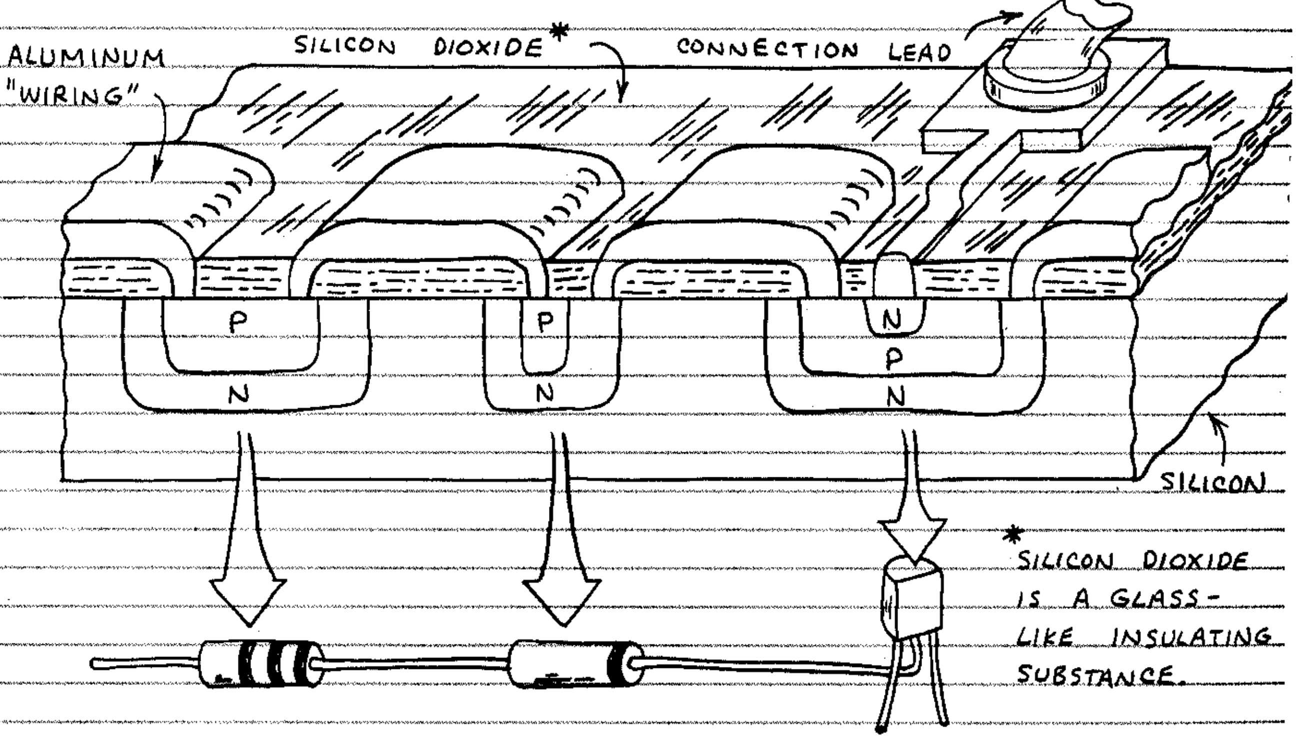
5. INTEGRATED CIRCUITS



ELECTRONIC CIRCUITS CAN BE MADE BY SIMULTANEOUSLY FORMING INDIVIDUAL TRANSISTORS, DIODES AND RESISTORS ON A SMALL CHIP OF SILICON. THE COMPONENTS ARE CONNECTED TO ONE ANOTHER WITH ALUMINUM "WIRES" DEPOSITED ON THE SURFACE OF THE CHIP. THE RESULT IS AN INTEGRATED CIRCUIT. INTEGRATED CIRCUITS (OR IC'S) CAN CONTAIN AS FEW AS SEVERAL TO AS MANY AS HUNDREDS OF THOUSANDS OF TRANSISTORS. THEY HAVE MADE POSSIBLE VIDEO GAMES, DIGITAL WATCHES, AFFORDABLE COMPUTERS AND MANY OTHER VERY SOPHISTICATED PRODUCTS. HERE'S A SIMPLIFIED AND HIGHLY MAGNIFIED VIEW OF A SECTION OF A *BIPOLAR* INTEGRATED CIRCUIT:



* SILICON DIOXIDE IS A GLASS-LIKE INSULATING SUBSTANCE.

RESISTOR — A SMALL SECTION OF P-TYPE SILICON FORMS A RESISTOR.

DIODE — A PN JUNCTION FORMS A DIODE.

TRANSISTOR — A PAIR OF PN JUNCTIONS FORMS AN NPN TRANSISTOR

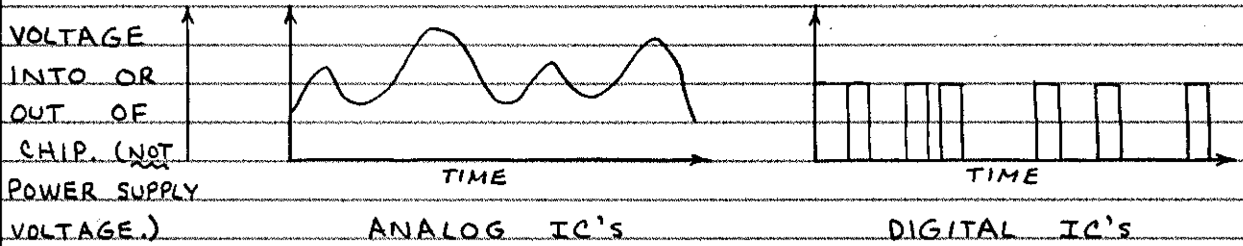
OF COURSE THE CONVENTIONAL COMPONENTS SHOWN BELOW THE HIGHLY MAGNIFIED SECTION OF THE IC ARE NOT DRAWN TO THE SAME SCALE. FOR EXAMPLE, ONE KIND OF IC INCLUDES 262,144 TRANSISTORS ON A SILICON CHIP ONLY ABOUT 1/4 INCH SQUARE!

☐ KINDS OF INTEGRATED CIRCUITS — INTEGRATED CIRCUITS ARE GROUPED INTO TWO MAJOR CATEGORIES:

1. ANALOG (OR LINEAR) IC'S PRODUCE, AMPLIFY OR RESPOND TO VARIABLE VOLTAGES. ANALOG IC'S INCLUDE MANY KINDS OF AMPLIFIERS, TIMERS, OSCILLATORS AND VOLTAGE REGULATORS.

2. DIGITAL (OR LOGIC) IC'S RESPOND TO OR PRODUCE SIGNALS HAVING ONLY TWO VOLTAGE LEVELS. DIGITAL IC'S INCLUDE MICROPROCESSORS, MEMORIES, MICROCOMPUTERS AND MANY KINDS OF SIMPLER CHIPS.

SOME IC'S COMBINE ANALOG AND DIGITAL FUNCTIONS ON A SINGLE CHIP. FOR EXAMPLE, A DIGITAL CHIP MAY INCLUDE A BUILT-IN ANALOG VOLTAGE REGULATOR SECTION. AND AN ANALOG TIMER CHIP MAY INCLUDE AN ON-CHIP DIGITAL COUNTER TO GIVE MUCH LONGER TIME DELAYS THAN POSSIBLE WITH THE TIMER ALONE.



☐ KINDS OF INTEGRATED CIRCUIT PACKAGES — IC CHIPS ARE SUPPLIED IN MANY DIFFERENT PACKAGES. BY FAR THE MOST COMMON ARE VARIATIONS OF THE DUAL IN-LINE PACKAGE (OR DIP). THE DIP IS MADE FROM PLASTIC (CHEAP) OR CERAMIC (MORE ROBUST). MOST DIPS HAVE 14 OR 16 PINS, BUT THE PIN COUNT CAN RANGE FROM 4 TO 64. HERE'S A TYPICAL DIP:

6. DIGITAL INTEGRATED CIRCUITS

NO MATTER HOW COMPLICATED, *ALL* DIGITAL INTEGRATED CIRCUITS ARE MADE FROM SIMPLE BUILDING BLOCKS CALLED *GATES*. GATES ARE LIKE ELECTRONICALLY CONTROLLED SWITCHES. THEY ARE EITHER *ON* OR *OFF*. HOW DO GATES WORK? LET'S START WITH THE BASICS...

MECHANICAL SWITCH GATES

THE THREE SIMPLEST GATES CAN BE DEMONSTRATED WITH SOME PUSHBUTTON SWITCHES, A BATTERY AND A LAMP.

THE 0 AND 1 INPUT (A & B) COMBINATIONS FORM NUMBERS IN THE TWO DIGIT (OR BIT) BINARY NUMBER SYSTEM. IN DIGITAL ELECTRONICS, BINARY NUMBERS SERVE AS CODES THAT REPRESENT DECIMAL NUMBERS, LETTERS OF THE ALPHABET, VOLTAGES AND MANY OTHER KINDS OF INFORMATION.

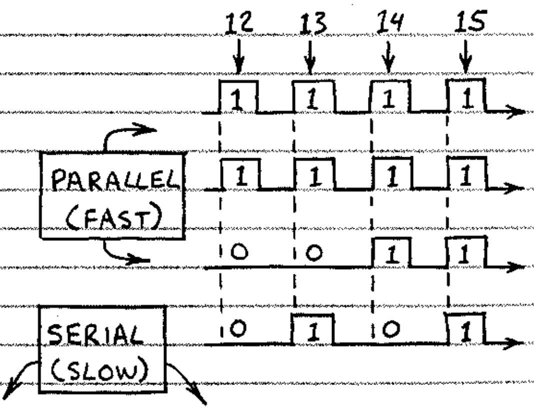
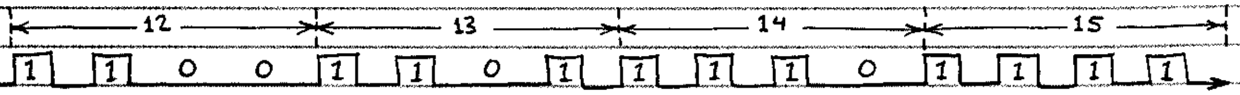
BINARY FACTS

A BINARY 0 OR 1 IS A BIT.
A PATTERN OF 4 BITS IS A NIBBLE.
A PATTERN OF 8 BITS IS A BYTE.

BCD— EACH DECIMAL DIGIT IS ASSIGNED ITS BINARY EQUIVALENT. NOTE THAT LEADING ZEROS ARE SHOWN. IN DIGITAL ELECTRONICS ALL BIT LOCATIONS ARE OCCUPIED.



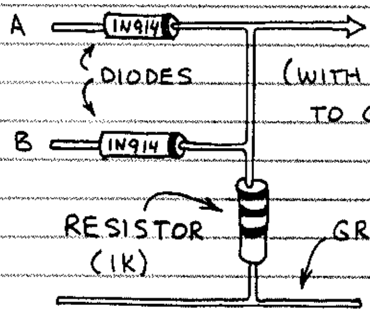
BINARY NUMBERS CAN BE SENT THROUGH WIRES (BUSES) ALL AT ONCE (PARALLEL) OR A BIT AT A TIME (SERIAL). SHOWN HERE ARE SERIAL AND PARALLEL TRANSMISSION OF 15... 14... 13... 12.



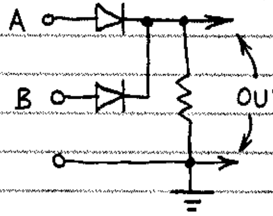
DIODE GATES

OFTEN IT'S DESIRABLE TO CONTROL A GATE ELECTRICALLY RATHER THAN MECHANICALLY. THE SIMPLEST ELECTRICALLY CONTROLLED GATE USES PN JUNCTION DIODES THAT ARE SWITCHED ON (FORWARD BIAS) OR OFF (REVERSE BIAS) BY AN INPUT SIGNAL OF SEVERAL VOLTS (BINARY 1 OR HIGH) OR AN INPUT NEAR OR AT GROUND (BINARY 0 OR LOW).

☐ DIODE "OR" GATE



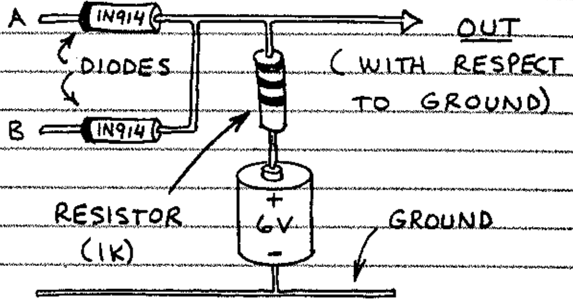
WHEN THE INPUT VOLTAGE AT A OR B IS MORE POSITIVE THAN GROUND, IT PASSES THROUGH THE FORWARD BIASED DIODE(S) AND APPEARS AT THE OUTPUT. OTHERWISE THE OUTPUT IS AT OR NEAR GROUND. THE TRUTH TABLE IS VALID FOR INPUTS OF 0 VOLT (0 OR LOW) AND +6 VOLTS (1 OR HIGH).



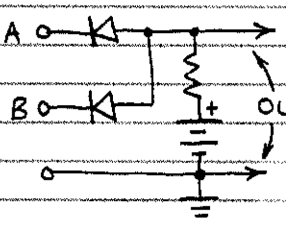
A	B	OUT
0V	0V	0V
0V	6V	5.4V
6V	0V	5.4V
6V	6V	5.4V

THE OUTPUT DOES NOT REACH A FULL 6 VOLTS WHEN HIGH BECAUSE THE DIODES REQUIRE A FORWARD VOLTAGE OF 0.6 VOLT. THIS VOLTAGE IS SUBTRACTED FROM THE OUTPUT VOLTAGE. (IN ELECTRONICS JARGON A SILICON DIODE CAUSES A "VOLTAGE DROP" OF 0.6 VOLT.)

☐ DIODE "AND" GATE



WHEN THE INPUT VOLTAGE AT A AND B IS MORE POSITIVE THAN GROUND, CURRENT FLOWS FROM THE BATTERY THROUGH THE RESISTOR TO THE OUTPUT. IF EITHER A OR B IS AT OR NEAR GROUND, ONE OR BOTH DIODES BECOME FORWARD BIASED AND CURRENT FLOWS AWAY FROM THE OUTPUT.



A	B	OUT
0V	0V	0V
0V	6V	.5V
6V	0V	.5V
6V	6V	5.4V

AS CIRCUITS BECOME MORE COMPLICATED, PICTORIAL VIEWS ARE NOT PRACTICAL. THAT'S WHY THIS PAGE INTRODUCES CIRCUIT DIAGRAMS FOR EACH OF THE TWO PICTORIALS SHOWN ABOVE. WE'LL FIND OUT MORE ABOUT CIRCUIT DIAGRAMS LATER. IN THE MEANTIME, THE NEXT PAGE SHOWS MORE OF THEM...

TRANSISTOR GATES

THE VOLTAGE DROP OF DIODE GATES MEANS AMPLIFICATION IS REQUIRED IN ORDER TO CONNECT TOGETHER A SERIES OF GATES. WHILE TRANSISTORS CAN PROVIDE THE NECESSARY AMPLIFICATION, TRANSISTORS CAN FUNCTION AS GATES! BOTH BIPOLAR AND FIELD-EFFECT TRANSISTORS CAN BE USED. ON THIS PAGE ARE SHOWN CIRCUIT DIAGRAMS FOR SOME OF THE SIMPLEST BIPOLAR TRANSISTOR GATES. TOGETHER THEY FORM THE RESISTOR-TRANSISTOR DIGITAL LOGIC FAMILY. YOU CAN ACTUALLY MAKE THESE GATES. BUT THE MAIN REASON THEY'RE HERE IS TO GIVE YOU AN APPRECIATION FOR THE INTEGRATED CIRCUIT GATES WE'LL BE LOOKING AT SHORTLY....

☐ "NOT" GATE (INVERTER)

WHEN IN IS AT +V (BINARY 1 OR HIGH), TRANSISTOR Q1 SWITCHES ON AND CONNECTS OUT DIRECTLY TO GROUND (BINARY 0 OR LOW). WHEN IN IS LOW, Q1 SWITCHES OFF AND OUT BECOMES (THROUGH R1) +V. "NOT" GATES LIKE THIS MAKE POSSIBLE IMPORTANT NEW LOGIC GATES.

☐ LOGIC GATES WITH MORE THAN TWO INPUTS — THE GATES SHOWN ABOVE ARE CALLED LOGIC CIRCUITS BECAUSE THEY MAKE LOGICAL DECISIONS. LOGIC GATES OFTEN HAVE MORE THAN TWO INPUTS. ADDITIONAL INPUTS INCREASE THE DECISION MAKING POWER OF A GATE. THEY ALSO INCREASE THE NUMBER OF WAYS GATES CAN BE CONNECTED TO ONE ANOTHER TO FORM ADVANCED DIGITAL LOGIC CIRCUITS. HERE ARE TWO EXAMPLES:

☐ SINGLE-INPUT GATES — THE "NOT" GATE OR INVERTER IS VERY IMPORTANT SINCE IT CAN *INVERT* (REVERSE) THE OUTPUT FROM ANOTHER GATE. STRICTLY SPEAKING, HOWEVER, THE INVERTER IS *NOT* A DECISION MAKING CIRCUIT (LIKE GATES WITH *TWO* OR MORE INPUTS). A CLOSE RELATIVE OF THE INVERTER IS THE *BUFFER*, A NON-INVERTING CIRCUIT THAT ISOLATES GATES FROM OTHER CIRCUITS OR ALLOWS THEM TO *DRIVE* HIGHER THAN NORMAL LOADS. THREE-STATE INVERTERS AND BUFFERS HAVE AN OUTPUT THAT CAN BE ELECTRONICALLY DISCONNECTED FROM THE REMAINDER OF THE CIRCUIT. THE OUTPUT IS THEN NEITHER HIGH NOR LOW. INSTEAD IT "FLOATS" AND APPEARS AS A *VERY* HIGH RESISTANCE.

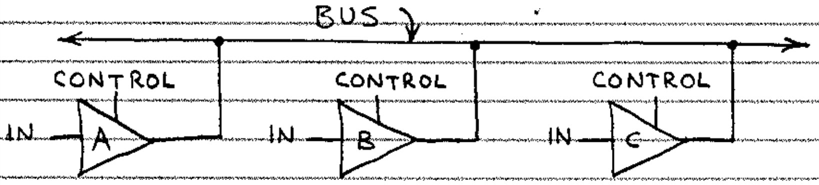
DATA "HIGHWAYS"

OFTEN CIRCUITS MADE FROM GATES EXCHANGE INFORMATION (BINARY 0'S AND 1'S ENCODED AS LOW AND HIGH VOLTAGE LEVELS). THE INFORMATION IS USUALLY SENT OVER WIRES CALLED *BUSES*. A BUS IS LIKE A *DATA HIGHWAY*. IT MAY BE ONE WIRE THROUGH WHICH INFORMATION IS SENT SERIALLY (BIT BY BIT). OR IT MAY BE UP TO EIGHT (OR MORE) WIRES THROUGH WHICH INFORMATION IS SENT IN PARALLEL (A BYTE OR MORE AT A TIME). IN BOTH CASES, OF COURSE, A GROUND IS REQUIRED TO COMPLETE THE CIRCUIT.

☐ 3-STATE TRAFFIC COPS — 3-STATE GATES CAN STOP "TRAFFIC JAMS" ON BUSES. FOR INSTANCE:



ONLY DATA ENTERING THE SELECTED BUFFER (CONTROL = L) GETS ON THE BUS.

HOW GATES ARE USED

GATES CAN BE USED INDIVIDUALLY OR CONNECTED TOGETHER TO FORM A "NETWORK" OF GATES CALLED A LOGIC CIRCUIT. ALMOST ALL LOGIC CIRCUITS CAN BE PLACED IN ONE OF TWO CATEGORIES: COMBINATIONAL OR SEQUENTIAL.

COMBINATIONAL LOGIC CIRCUITS

COMBINATIONAL LOGIC CIRCUITS RESPOND TO INCOMING DATA (0'S AND 1'S) ALMOST IMMEDIATELY AND WITHOUT REGARD TO EARLIER EVENTS. (THIS WILL MAKE MORE SENSE WHEN YOU READ ABOUT SEQUENTIAL CIRCUITS...) COMBINATIONAL LOGIC CIRCUITS CAN BE VERY SIMPLE OR IMMENSELY COMPLICATED. VIRTUALLY ANY COMBINATIONAL CIRCUIT CAN BE IMPLEMENTED WITH ONLY "NAND" OR "NOR" GATES. LIKE THESE "NAND" GATE CIRCUITS...

SEQUENTIAL LOGIC CIRCUITS

THE OUTPUT STATE OF A SEQUENTIAL LOGIC CIRCUIT IS DETERMINED BY THE PREVIOUS STATE OF THE INPUT. IN OTHER WORDS, BITS OF DATA MOVE THROUGH SEQUENTIAL CIRCUITS STEP-BY-STEP. OFTEN THE DATA ADVANCES ONE STEP WHEN A PULSE IS RECEIVED FROM A "CLOCK" (A CIRCUIT THAT EMITS A STEADY STREAM OF PULSES). THE SEQUENTIAL LOGIC BUILDING BLOCK IS THE FLIP-FLOP. HERE'S A QUICK FLIP-FLOP REVIEW:

☐ THE BASIC "RS" (RESET-SET) FLIP-FLOP

ALSO CALLED A LATCH. THE OUTPUTS (Q AND $\bar{Q}$) ARE ALWAYS IN OPPOSITE STATES. ($\bar{Q}$ MEANS "NOT Q".)

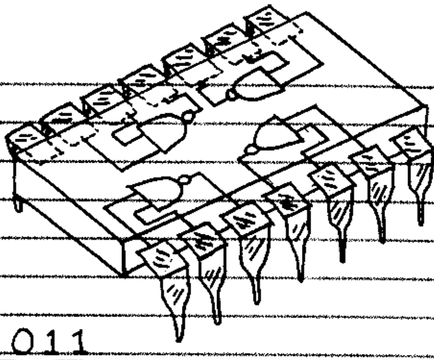
DIGITAL IC FAMILIES



4011

A "QUAD" (FOUR) OF 2-INPUT CMOS "NAND" GATES

THERE ARE MORE THAN A DOZEN MAJOR FAMILIES OF BIPOLAR AND MOS INTEGRATED CIRCUITS. EACH IC (OR "CHIP") CONTAINS A SPECIFIC LOGIC NETWORK OR ASSORTMENT OF VARIOUS LOGIC FUNCTIONS. HERE ARE SOME OF THE MAJOR DIGITAL IC FAMILIES:

☐ BIPOLAR DIGITAL IC'S

1. TRANSISTOR-TRANSISTOR LOGIC (TTL OR T^2L). THE LARGEST AND FORMERLY MOST POPULAR DIGITAL IC FAMILY. CAN CHANGE STATES MORE THAN 20,000,000 TIMES PER SECOND. VERY INEXPENSIVE. DRAWBACKS: MUST BE POWERED BY 5-VOLT SUPPLY. USES LOTS OF POWER. (INDIVIDUAL GATES REQUIRE 3 OR 4 MILLIAMPERES.) MOST WIDELY USED IS THE 7400 SERIES. THE 7404, FOR EXAMPLE, CONTAINS FOUR INVERTERS.

2. LOW-POWER SCHOTTKY TTL (LS). A NEWER KIND OF TTL THAT CONSUMES ONLY 20% AS MUCH POWER. DRAWBACK: MORE EXPENSIVE THAN STANDARD TTL. MOST WIDELY USED IS THE 74LS00 SERIES.

☐ MOSFET DIGITAL IC'S

1. P- AND N-CHANNEL MOS (PMOS AND NMOS). CONTAIN MORE GATES PER CHIP THAN TTL. MANY SPECIAL PURPOSE CHIPS (MICROPROCESSORS, MEMORIES, ETC.). DRAWBACKS: FEW COUNTERPARTS TO POPULAR TTL CHIPS. SLOWER THAN TTL. MAY REQUIRE TWO OR MORE SUPPLY VOLTAGES. MAY BE DAMAGED BY STATIC ELECTRICAL DISCHARGE.

2. COMPLEMENTARY MOS (CMOS). FASTEST GROWING AND MOST VERSATILE DIGITAL IC FAMILY. THERE ARE CMOS VERSIONS OF MOST POPULAR TTL CHIPS. ONE SERIES USES THE SAME DESIGNATION NUMBERS. THE 74C04, FOR EXAMPLE, IS THE CMOS EQUIVALENT OF THE TTL 7404. NEW HIGH-SPEED CMOS JUST AS FAST AS TTL. MOST CMOS HAS A WIDE SUPPLY VOLTAGE RANGE (TYPICALLY +3 TO +18 VOLTS). USES LESS POWER THAN ANY OTHER DIGITAL IC FAMILY. (INDIVIDUAL GATES REQUIRE 0.1 MILLIAMPERE.) DRAWBACK: MAY BE DAMAGED BY STATIC ELECTRICAL DISCHARGE. MOST WIDELY USED ARE 74C00 AND 4000 SERIES.

7. LINEAR INTEGRATED CIRCUITS

THE INPUT AND OUTPUT VOLTAGE LEVELS OF LINEAR INTEGRATED CIRCUITS CAN VARY OVER A WIDE RANGE. OFTEN THE OUTPUT VOLTAGE IS PROPORTIONAL TO THE INPUT VOLTAGE. THEREFORE, A GRAPH OF INPUT VERSUS OUTPUT IS A STRAIGHT (LINEAR) LINE. THERE ARE MANY TYPES OF LINEAR IC'S. ONLY THE MAJOR TYPES ARE COVERED HERE. FIRST LET'S COMPARE THE BASIC DIGITAL AND LINEAR CIRCUITS:

THE BASIC LINEAR CIRCUIT

A SINGLE BIPOLAR OR FIELD-EFFECT TRANSISTOR CAN FUNCTION AS A DIGITAL OR LINEAR CIRCUIT. IN BOTH CASES, THE TRANSISTOR CAN INVERT THE SIGNAL AT ITS INPUT. HERE'S HOW AN NPN BIPOLAR TRANSISTOR CAN PERFORM ALL FOUR FUNCTIONS:

DIGITAL:

HERE TRANSISTOR Q1 IS USED AS A SWITCH. WHEN THE INPUT IS NEAR +V (OR HIGH), Q1 TURNS ON AND LED 1 IS ILLUMINATED. WHEN THE INPUT IS NEAR GROUND (OR LOW), Q1 TURNS OFF. THIS TURNS LED 1 OFF AND ALLOWS LED 2 TO GLOW. (R2 CONTROLS THE CURRENT THROUGH BOTH LEDs.) THIS CIRCUIT IS THEN A COMBINED DIGITAL BUFFER AND INVERTER.

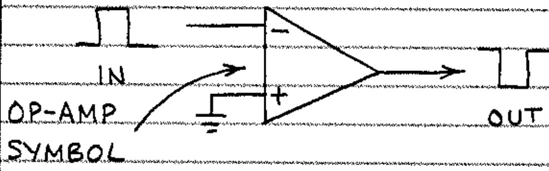
LINEAR:

HERE Q2 IS AN AMPLIFIER THAT OPERATES OVER THE ENTIRE RANGE FROM FULL OFF TO FULL ON. R4 AND R5 FORM A VOLTAGE DIVIDER THAT APPLIES A SMALL VOLTAGE TO Q2'S BASE TO KEEP Q2 SLIGHTLY ON EVEN WHEN NO INPUT IS PRESENT. THIS ALLOWS Q2 TO OPERATE IN A LINEAR MODE. AS THE INPUT VOLTAGE RISES, LED 3 BRIGHTENS AND LED 4 DIMS.

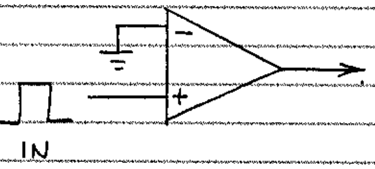
OPERATIONAL AMPLIFIERS

OPERATIONAL AMPLIFIERS (OR "OP-AMPS") ARE BY FAR THE MOST VERSATILE OF LINEAR IC'S. THEY'RE CALLED "OPERATIONAL" AMPLIFIERS SINCE THEY WERE ORIGINALLY DESIGNED TO DO MATHEMATICAL OPERATIONS. OP-AMPS AMPLIFY THE DIFFERENCE BETWEEN VOLTAGES OR SIGNALS (AC OR DC) APPLIED TO THEIR TWO INPUTS. THE VOLTAGE APPLIED TO ONLY ONE INPUT WILL BE AMPLIFIED IF THE SECOND INPUT IS GROUNDED OR MAINTAINED AT SOME VOLTAGE LEVEL.

☐ OP-AMP OPERATION — THE OP-AMP HAS AN INVERTING AND NON-INVERTING INPUT. THE POLARITY OF A VOLTAGE APPLIED TO THE INVERTING INPUT IS REVERSED AT THE OUTPUT. (INVERTING INPUT IS − ; NON-INVERTING INPUT IS +.)



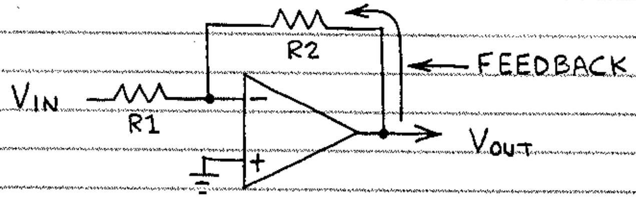
INVERTING MODE



NON-INVERTING MODE

P.122

☐ OP-AMP "FEEDBACK" — THE CIRCUITS SHOWN ABOVE ALLOW THE OP-AMP TO OPERATE AT ITS MAXIMUM AMPLIFICATION LEVEL (OR GAIN). USUALLY THE GAIN IS REDUCED TO A MORE PRACTICAL LEVEL BY FEEDING SOME OF THE OUTPUT BACK TO THE INVERTING (−) INPUT. FOR EXAMPLE:



INVERTING AMPLIFIER

GAIN = R2/R1

$V_{OUT} = -V_{IN}(R2/R1)$

P.122

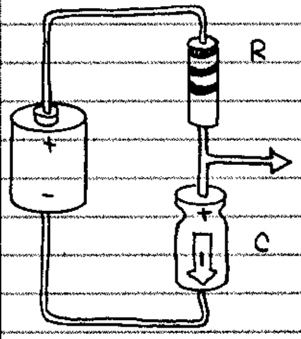
☐ OP-AMP COMPARATOR — WHEN OPERATED WITHOUT A FEEDBACK RESISTOR (R2 ABOVE), THE OUTPUT VOLTAGE WILL SWING FROM FULL ON TO FULL OFF (OR VICE VERSA) WHEN THE VOLTAGES APPLIED TO THE INPUTS DIFFER BY ONLY ABOUT 0.001 VOLT! THIS DIGITAL-LIKE MODE MAKES POSSIBLE MANY USEFUL APPLICATIONS.

P.124

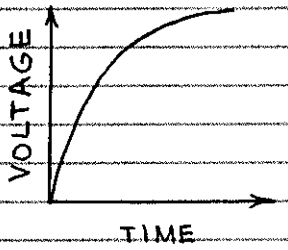
☐ TYPES OF OP-AMPS — BOTH BIPOLAR AND MOSFET IC OP-AMPS ARE AVAILABLE. SOME BIPOLAR OP-AMPS HAVE FET OR MOSFET INPUTS TO PROVIDE VERY HIGH INPUT RESISTANCE. MANY DIFFERENT OP-AMPS ARE MADE. A SINGLE IC MAY INCLUDE UP TO FOUR INDIVIDUAL OP-AMPS.

TIMERS

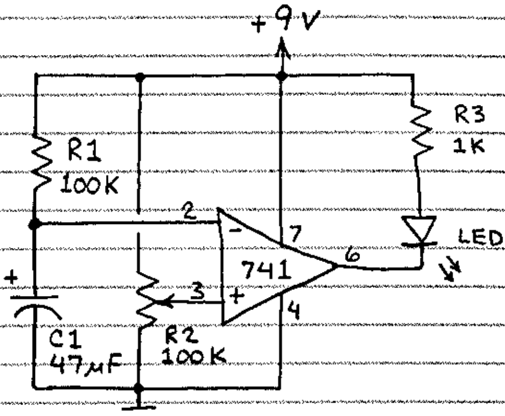
WHEN OPERATED AS A COMPARATOR, THE OP-AMP CAN BE USED AS A TIMER. ALL THAT'S REQUIRED IS AN RC (RESISTOR-CAPACITOR) CIRCUIT LIKE THIS:



RC CIRCUIT



RC CHARGING GRAPH



TIMER

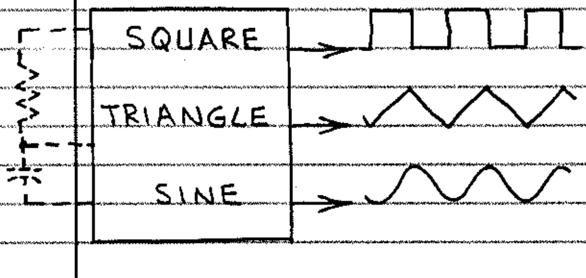
IN THE CIRCUIT DIAGRAM (ABOVE RIGHT), R1 AND C1 FORM AN RC CIRCUIT. C1 GRADUALLY CHARGES TO +9 VOLTS THROUGH R1. WHEN THE VOLTAGE ON C1 EXCEEDS THE REFERENCE VOLTAGE SUPPLIED TO THE NON-INVERTING INPUT OF THE OP-AMP, ITS OUTPUT SWINGS FROM HIGH TO LOW AND THE LED GLOWS. THE TIME DELAY CAN BE CHANGED BY ALTERING THE VALUES OF R1 AND C1 OR THE SETTING OF R2. DISCHARGE C1 (USE PUSHBUTTON SWITCH) FOR NEW CYCLE.

☐ IC TIMERS — THE SIMPLE CIRCUIT ABOVE IS THE KEY INGREDIENT OF MOST IC TIMERS. MOST INCLUDE AN OUTPUT FLIP-FLOP TO GIVE DEFINITE HIGH OR LOW OUTPUT. SOME INCLUDE A BINARY COUNTER THAT ADVANCES ONE COUNT PER DELAY PERIOD (OR CYCLE). THE TIMER IS RECYCLED EACH TIME THE COUNT ADVANCES. A DECODER AT THE COUNTER OUTPUT ALLOWS TOTAL DELAYS OF FROM DAYS TO A YEAR OR MORE TO BE SELECTED. BOTH BIPOLAR AND CMOS TIMERS ARE AVAILABLE.

P.126

FAMOUS FACT: ANALOG COMPUTERS USE OP-AMPS TO SOLVE COMPLEX EQUATIONS!

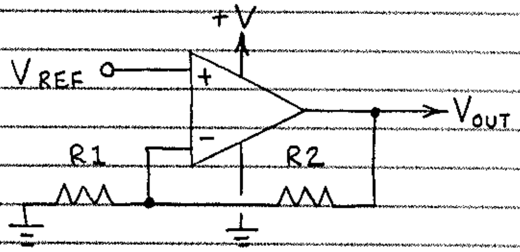
FUNCTION GENERATORS



THESE IC'S GENERATE VARIOUS KINDS OF OUTPUT WAVES SUCH AS THOSE SHOWN HERE. THE FREQUENCY OF THE WAVES CAN BE CONTROLLED BY AN EXTERNAL RC CIRCUIT.

VOLTAGE REGULATORS

VOLTAGE REGULATORS CONVERT A VOLTAGE APPLIED TO THEIR INPUT INTO A FIXED OR VARIABLE (BUT USUALLY LOWER) VOLTAGE. IN MOST A SMALL, FIXED REFERENCE VOLTAGE (USUALLY A VOLT OR SO) IS APPLIED TO THE NON-INVERTING INPUT OF AN OP-AMP. THE RERERENCE VOLTAGE (OR V_{REF}) IS THEN AMPLIFIED BY THE RATIO OF THE FEEDBACK AND INPUT RESISTORS (THE GAIN). IF ONE OF THE RESISTORS IS A POTENTIOMETER, THE OUTPUT VOLTAGE (V_{OUT}) CAN BE VARIED FROM V_{REF} TO +V (THE CHIP SUPPLY VOLTAGE). ACTUAL IC REGULATORS INCLUDE EXTRA TRANSISTORS TO PROVIDE V_{REF} AND TO ALLOW THE CHIP TO DRIVE LOADS THAT REQUIRE MORE POWER THAN AN OP-AMP ALONE CAN DELIVER.



BASIC VOLTAGE REGULATOR

☐ IC REGULATORS — MANY TYPES OF FIXED AND VARIABLE OUTPUT IC REGULATORS ARE AVAILABLE. MOST ARE INSTALLED IN PACKAGES MADE OF METAL OR HAVING METAL TABS TO HELP RADIATE EXCESSIVE HEAT INTO THE SURROUNDING AIR. CAUTION: MANUFACTURER'S OPERATING INSTRUCTIONS AND STANDARD SAFETY PRECAUTIONS MUST BE FOLLOWED FOR BEST RESULTS.

P.125

OTHER LINEAR IC's

THERE ARE NUMEROUS SPECIAL FUNCTION LINEAR IC's, MANY OF WHICH INCORPORATE OP-AMPS. FOR EXAMPLE:

☐ AUDIO AMPLIFIERS — MANY KINDS AVAILABLE. SOME INCLUDE TWO AMPLIFIERS ON ONE CHIP (FOR STEREO).

☐ PHASE-LOCKED LOOPS — BASED ON AN OLD BUT CLEVER IDEA IN WHICH AN ON-CHIP OSCILLATOR DUPLICATES (OR TRACKS) THE FREQUENCY OF AN INCOMING SIGNAL. USED TO DETECT THE PRESENCE OF CERTAIN FREQUENCIES (LIKE TOUCH-TONE® TONES) AND TO DEMODULATE FM RADIO SIGNALS.

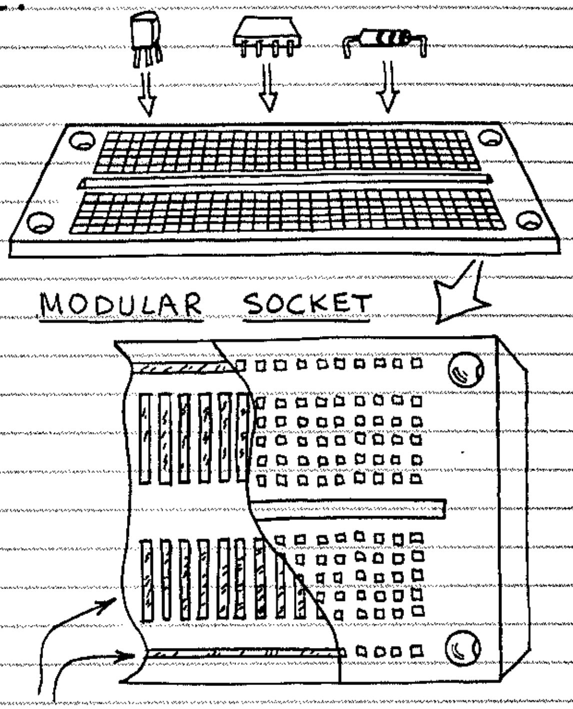
☐ OTHER LINEAR IC's — INCLUDED ARE MANY KINDS OF CHIPS FOR TELEPHONE, RADIO, TELEVISION AND COMPUTER COMMUNICATIONS. ALSO, MANY KINDS OF IC's THAT DETECT TEMPERATURE, LIGHT AND PRESSURE.

8. CIRCUIT ASSEMBLY TIPS

THERE ARE SEVERAL WAYS TO MAKE EITHER TEMPORARY OR PERMANENT VERSIONS OF ELECTRONIC CIRCUITS. IN THIS CHAPTER WE'LL LOOK AT SOME CIRCUIT ASSEMBLY TIPS YOU MAY FIND HELPFUL.

TEMPORARY CIRCUITS

IT'S ALWAYS WISE TO BUILD A TEMPORARY VERSION OF A CIRCUIT BEFORE ASSEMBLING IT IN PERMANENT FORM. YOU CAN THEN MAKE CHANGES AND FIND OUT HOW WELL THE CIRCUIT WORKS. BY FAR THE MOST IMPORTANT TOOL FOR TEMPORARY CIRCUIT ASSEMBLY IS THE PLASTIC SOLDERLESS MODULAR BREADBOARD SOCKET. IT'S A GOOD IDEA TO KEEP SEVERAL ON YOUR WORKBENCH. THEY WILL LET YOU BUILD ENTIRE CIRCUITS IN MINUTES. USE "JUMPER" WIRES TO INTERCONNECT PARTS WHOSE LEADS ARE NOT INSERTED IN THE SAME ROW OF TERMINALS. TO AVOID BENDING THEIR PINS (AND PRICKING YOUR FINGERS), INSTALL AND REMOVE IC'S CAREFULLY.



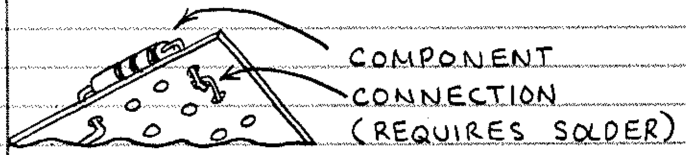
CUTAWAY SHOWING COMMON TERMINAL CONNECTIONS.

HINT: INSTALL SOCKET ON BASE AND ADD POTENTIOMETERS, BATTERY, LEDs, SWITCHES, ETC.

PERMANENT CIRCUITS

WITH THE EXCEPTION OF SOME VERY SIMPLE CIRCUITS, MOST PERMANENT CIRCUITS ARE ASSEMBLED ON SOME FORM OF CIRCUIT BOARD.

☐ PERFORATED BOARD CONSTRUCTION — COMPONENT LEADS ARE INSERTED THROUGH PERFORATIONS IN A PHENOLIC OR SIMILAR BOARD AND SOLDERED TOGETHER ON THE BACK SIDE OF THE BOARD. OFTEN INSULATED CONNECTION WIRES MUST BE USED. ONCE ASSEMBLED, "PERFBOARD" CIRCUITS ARE DIFFICULT TO REPAIR SINCE COMPONENT LEADS ARE OFTEN TWISTED AND SOLDERED.



☐ WIRE-WRAP — FASTEST WAY TO ASSEMBLE CIRCUITS THAT USE MORE THAN A FEW IC'S. USE WIRE-WRAP IC SOCKETS (WITH SQUARE CONNECTION PINS). BOTH HAND AND MOTOR POWERED WRAPPING TOOLS ARE AVAILABLE. IF YOU USE THE KIND THAT REQUIRES SOME OF THE WIRE'S INSULATION BE REMOVED, WRAP A FEW TURNS OF INSULATED WIRE AROUND THE CONNECTION PIN TO STRENGTHEN THE CONNECTION.

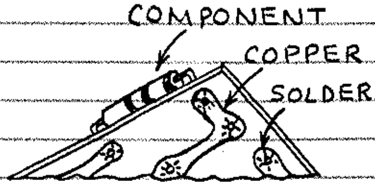
WIRE-WRAPPING "BIT"

☐ PRINTED CIRCUIT (PC) — PROVIDES THE NEATEST AND MOST PROFESSIONAL APPEARING COMPLETED CIRCUIT. SOCKETS NOT REQUIRED, BUT COMPONENT LEADS MUST BE SOLDERED TO THE COPPER PATTERNS ON THE BOARD. THERE ARE MANY TYPES OF PC BOARDS. TWO TYPES USED BY EXPERIMENTERS ARE:

1. PRE-ETCHED PERFORATED GRID BOARDS HAVE A ROUND, COPPER FOIL SOLDER PAD AT EACH HOLE. ON MANY BOARDS ROWS OF HOLES ARE CONNECTED BY COMMON COPPER FOIL STRIPS (LIKE A SOLDERLESS BREADBOARD). IT'S USUALLY NECESSARY TO JOIN SOME OF THE CONTACTS ON THE BOARD WITH "JUMPERS" (SHORT LENGTHS OF INSULATED HOOKUP OR WRAPPING WIRE).

2. CUSTOM PC BOARDS ARE MADE BY APPLYING A TAPE OR CHEMICAL COATING (THE "RESIST") TO THE CLEAN COPPER FOIL OF A PC BOARD. THE UNCOATED COPPER IS THEN CHEMICALLY ETCHED AWAY, LEAVING BEHIND A FOIL WIRING PATTERN. HOLES ARE DRILLED FOR COMPONENT LEADS. TAKES LOTS OF TIME, BUT PRODUCES NEAT CIRCUITS.



COMPONENT
COPPER
SOLDER

HOW TO SOLDER

GOOD SOLDERING PRACTICES ARE ESSENTIAL FOR RELIABLE OPERATION OF A CIRCUIT WITH SOLDERED CONNECTIONS. HERE ARE SIX STEPS FOR SUCCESSFUL SOLDERING:

1. ALWAYS USE A LOW-WATTAGE SOLDERING IRON (25 TO 40 WATTS). BE SURE TO TIN THE TIP ACCORDING TO THE MANUFACTURER'S INSTRUCTIONS.

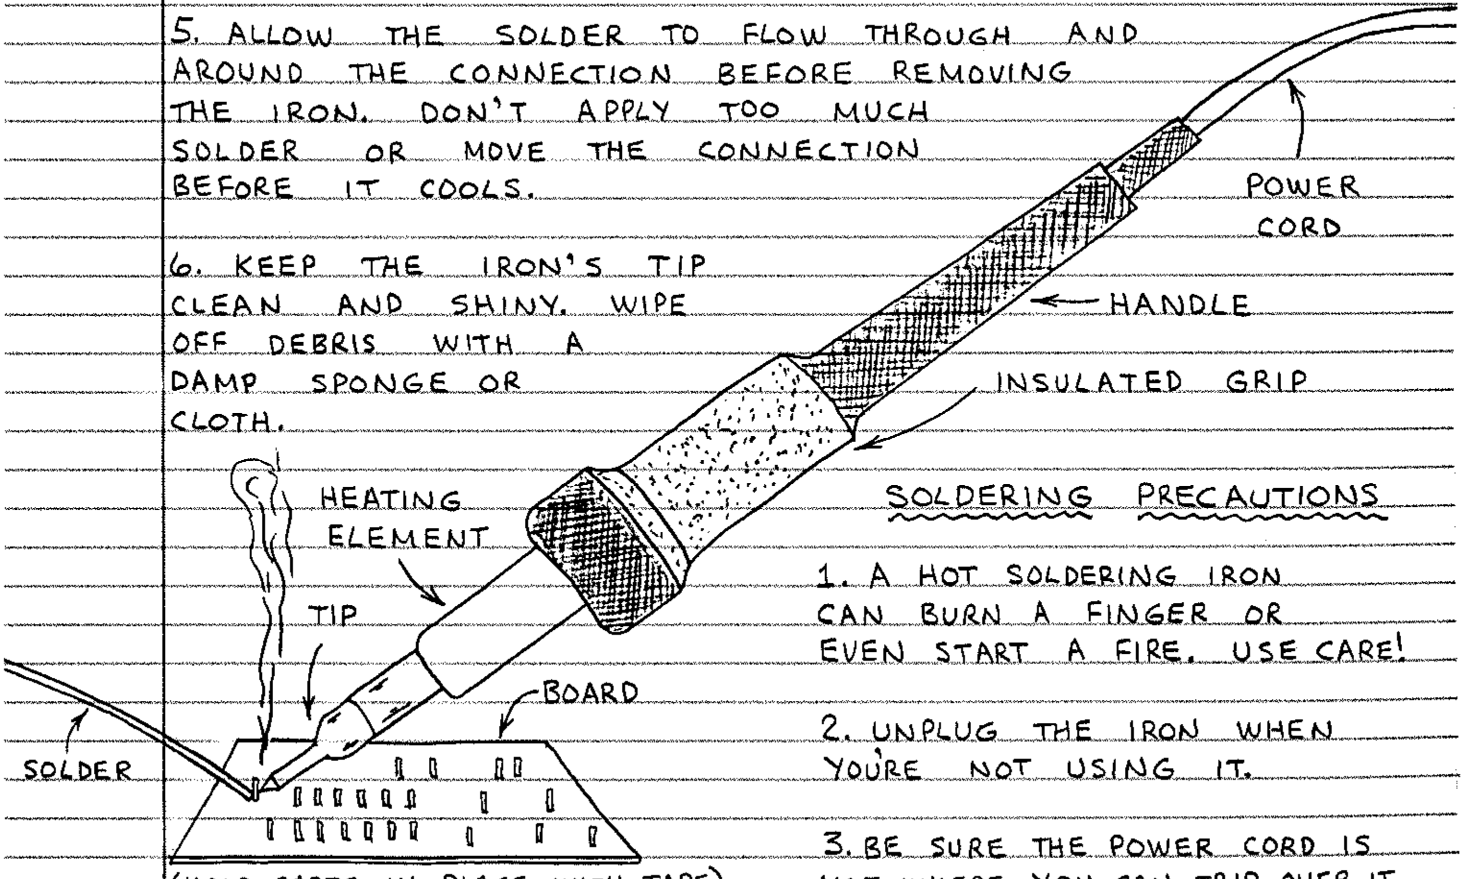
2. ALWAYS USE ROSIN CORE SOLDER WHEN SOLDERING ELECTRONIC COMPONENTS. NEVER USE ACID CORE SOLDER SINCE IT WILL CORRODE THE SOLDERED LEAD.

3. SOLDER DOES NOT ADHERE TO PAINT, GREASE, OIL, WAX OR MELTED INSULATION. REMOVE ALL SUCH FOREIGN MATTER WITH A SOLVENT, STEEL WOOL OR FINE SANDPAPER. ALWAYS BUFF THE COPPER FOIL OF A PC BOARD WITH STEEL WOOL BEFORE SOLDERING. (THE COPPER SHOULD BE SHINY.)

4. TO SOLDER, FIRST HEAT THE CONNECTION (NOT THE SOLDER!) FOR A FEW SECONDS WITH THE HOT TIP OF THE IRON. THEN LEAVE THE IRON IN PLACE AND APPLY SOLDER.

5. ALLOW THE SOLDER TO FLOW THROUGH AND AROUND THE CONNECTION BEFORE REMOVING THE IRON. DON'T APPLY TOO MUCH SOLDER OR MOVE THE CONNECTION BEFORE IT COOLS.

6. KEEP THE IRON'S TIP CLEAN AND SHINY. WIPE OFF DEBRIS WITH A DAMP SPONGE OR CLOTH.



(HOLD PARTS IN PLACE WITH TAPE)

SOLDERING PRECAUTIONS

1. A HOT SOLDERING IRON CAN BURN A FINGER OR EVEN START A FIRE. USE CARE!

2. UNPLUG THE IRON WHEN YOU'RE NOT USING IT.

3. BE SURE THE POWER CORD IS NOT WHERE YOU CAN TRIP OVER IT.

POWERING ELECTRONIC CIRCUITS

☐ BATTERY POWER — MANY CIRCUITS USE SO LITTLE POWER THEY CAN BE POWERED BY BATTERIES. THIS KEEPS THE COMPLETED CIRCUIT COMPACT AND ALLOWS IT TO BE OPERATED ANYWHERE.

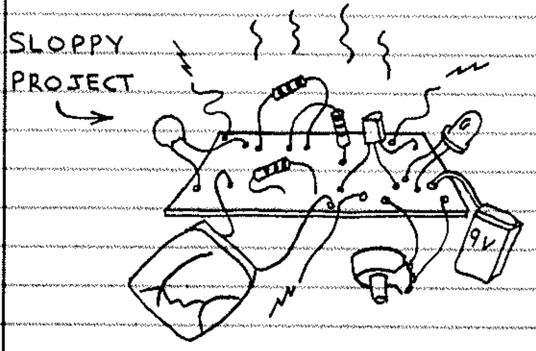
☐ SOLAR POWER — SOLAR CELLS CAN POWER YOUR CIRCUITS DIRECTLY. OR YOU CAN USE AN ARRAY OF SOLAR CELLS TO CHARGE A RECHARGEABLE BATTERY.

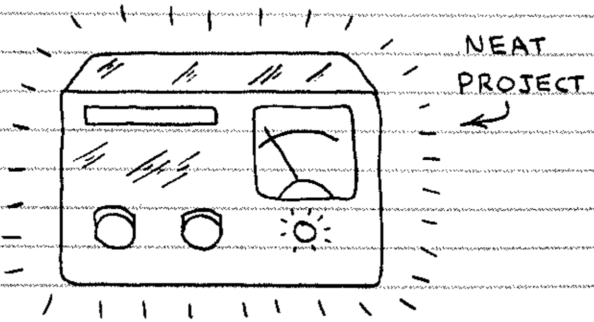
☐ LINE POWER - THE SIMPLEST LINE POWERED SUPPLY IS THE SO-CALLED AC ADAPTER. THESE MODULAR UNITS ARE COMPACT AND EASY TO USE. UNITS HAVING VARIOUS OUTPUT VOLTAGES AND CURRENTS ARE AVAILABLE. YOU CAN MAKE YOUR OWN LINE POWERED SUPPLY USING AN IC VOLTAGE REGULATOR.

☐ CAUTION — SAFETY SHOULD BE YOUR FIRST CONCERN WHEN BUILDING YOUR OWN LINE POWERED SUPPLY. THE POWER CORD MUST BE PROTECTED FROM THE SHARP EDGES OF A HOLE DRILLED IN A METAL CABINET. (USE A PLASTIC STRAIN RELIEF.) ALL CONNECTIONS TO THE AC LINE MUST BE INSIDE A FULLY ENCLOSED HOUSING! LEAVING SUCH CONNECTIONS EXPOSED IS A POTENTIAL SHOCK HAZARD. MAKE SURE ALL COMPONENTS THAT ARE CONNECTED TO THE AC LINE (SWITCHES, FUSES, TRANSFORMERS, ETC.) MEET OR EXCEED THE POWER REQUIREMENT OF YOUR CIRCUIT.

SUMMING UP CIRCUIT ASSEMBLY

THE REMAINDER OF THIS BOOK INCLUDES MANY CIRCUITS YOU CAN QUICKLY ASSEMBLE ON A SOLDERLESS BREADBOARD. CHANCES ARE YOU'LL WANT TO MAKE PERMANENT VERSIONS OF SOME. FOR BEST RESULTS, PLAN THE PROJECT CAREFULLY. A NEATLY ASSEMBLED PROJECT WILL BE MORE RELIABLE THAN ONE HASTILY ASSEMBLED.





9. 100 ELECTRONIC CIRCUITS

HERE'S A COLLECTION OF 100 ELECTRONIC CIRCUITS. I'VE ASSEMBLED EACH CIRCUIT TO MAKE SURE ALL OF THEM WORK.

☐ SELECTING AND SUBSTITUTING COMPONENTS — YOU CAN FIND MOST OF THE COMPONENTS AT RADIO SHACK STORES. SAVE TIME AND MAKE A LIST OF WHAT YOU NEED BEFORE YOU VISIT RADIO SHACK. (YOU CAN FIND CURRENT CATALOG NUMBERS IN THE LATEST RADIO SHACK CATALOG.) IF A COMPONENT IS UNAVAILABLE, TRY ELSEWHERE. SOMETIMES YOU CAN SUBSTITUTE COMPONENTS. FOR EXAMPLE, IT'S OFTEN OK TO SUBSTITUTE NPN SWITCHING TRANSISTORS FOR ONE ANOTHER (2N3904 FOR 2N2222, ETC.). NEARBY VALUES OF RESISTORS AND CAPACITORS CAN OFTEN BE USED (1.2K FOR 1K RESISTOR, 0.33 μF FOR 0.47 μF CAPACITOR, ETC.). ALWAYS FOLLOW APPROPRIATE VOLTAGE AND POWER RATINGS!

☐ WHEN A CIRCUIT DOESN'T WORK — MAKE SURE THE CIRCUIT IS RECEIVING ADEQUATE POWER. IF IT IS OR IF YOU SMELL OR FEEL A HOT COMPONENT, IMMEDIATELY DISCONNECT THE POWER AND FOLLOW THESE STEPS: ① RECHECK ALL CONNECTIONS. (IS A WIRE MISSING? IS AN IC PIN BENT? IS A SOLDER CONNECTION BAD? IS A WIRE "SHORTED"? IS A DIODE BACKWARDS?) ② IS A COMPONENT DEFECTIVE? ③ SOMETIMES, ESPECIALLY WHEN POWER SUPPLY LEADS ARE MORE THAN SIX INCHES LONG, IC CIRCUITS WILL WORK IMPROPERLY OR NOT AT ALL UNLESS YOU CONNECT A 0.1 μF CAPACITOR ACROSS THE POWER SUPPLY PINS OF EACH CHIP. IT MAY ALSO BE NECESSARY TO CONNECT A 1 TO 10 μF CAPACITOR ACROSS THE POWER LEADS WHERE THEY ENTER THE BOARD. ④ DOES THE PUBLISHED CIRCUIT CONTAIN AN ERROR?

☐ SAFETY FIRST — BE SURE TO FOLLOW APPROPRIATE PRECAUTIONS WHEN WORKING WITH AC LINE POWERED CIRCUITS. BE CAREFUL WHEN SOLDERING. CIRCUITS WITH SPEAKERS CAN PRODUCE VERY LOUD SOUNDS. KEEP YOUR DISTANCE, AND DON'T USE HEADPHONES.

☐ GOING FURTHER — TRY EXPERIMENTING WITH THE VALUES OF COMPONENTS IN RC CIRCUITS (P. 37). TRY SUBSTITUTING OTHER OUTPUT DEVICES IN CIRCUITS THAT DRIVE A RELAY, PIEZO BUZZER, ETC. (BE SURE TO FOLLOW VOLTAGE AND CURRENT RATINGS. USE OHM'S LAW AND, IF NECESSARY, ADD A SERIES RESISTOR TO REDUCE CURRENT.) BEFORE BUILDING A PERMANENT VERSION OF A CIRCUIT, ALWAYS ASSEMBLE AND TEST A BREADBOARD VERSION. FINALLY, BE SURE TO BUY RADIO SHACK'S CURRENT "SEMICONDUCTOR REFERENCE GUIDE" AND "ENGINEER'S NOTEBOOK." FOR MORE ADVANCED CIRCUITS AND INFORMATION ABOUT NEW DEVELOPMENTS, READ MY COLUMN ("THE ELECTRONICS SCIENTIST") IN COMPUTERS & ELECTRONICS.

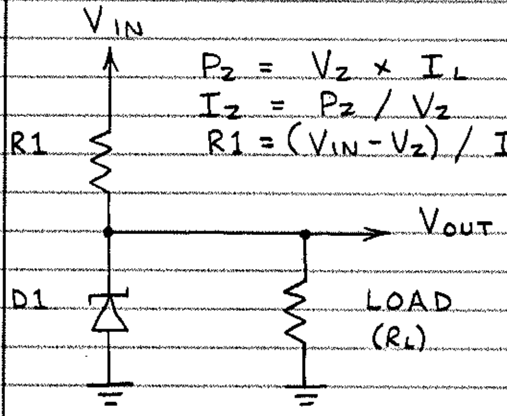
ZENER DIODE CIRCUITS

☐ VOLTAGE REGULATOR



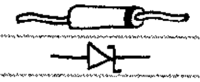
$P_Z = V_Z \times I_L$

$I_Z = P_Z / V_Z$

$R1 = (V_{IN} - V_Z) / I$

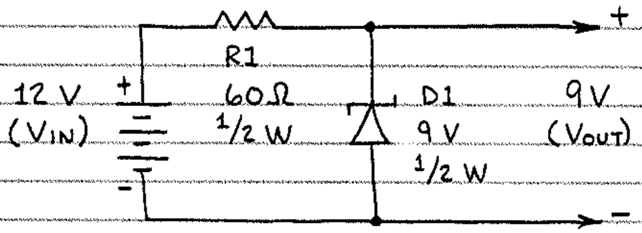
I_L = MAXIMUM LOAD CURRENT
I_Z = MAXIMUM ZENER CURRENT
I = CURRENT THROUGH R1
V_Z = ZENER DIODE VOLTAGE
P_Z = ZENER DIODE POWER

THIS CIRCUIT SUPPLIES A STEADY VOLTAGE (V_{OUT}) TO A LOAD FROM AN UNREGULATED SUPPLY (LIKE A BATTERY). V_{IN} CAN VARY BUT MUST BE AT LEAST 1 VOLT ABOVE DESIRED V_{OUT}. I_L CAN VARY FROM 0 MA TO PLANNED MAXIMUM VALUE. I DOES NOT CHANGE IF I_L FALLS TO 0 MA. SINCE $I = I_L + I_Z$, I_Z RISES AS I_L FALLS. IN OTHER WORDS, THE REGULATOR ALWAYS USES THE SAME CURRENT, EVEN WHEN THE LOAD IS REMOVED. CAUTION: D1 AND R1 MUST HAVE PROPER POWER RATING. USE OHM'S LAW (P. 14).

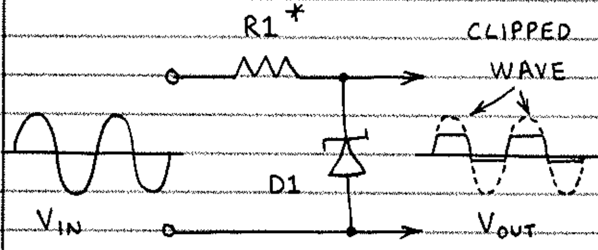


EXAMPLE: A RADIO DRAWS FROM 20 TO 50 MA FROM A 9 VOLT BATTERY. TO POWER IT FROM A 12 VOLT BATTERY, USE A 9 VOLT, 1/2 WATT ZENER DIODE. R1 SHOULD BE CLOSE TO 60 Ω AND RATED FOR AT LEAST 0.15 W.

EXAMPLE CIRCUIT:

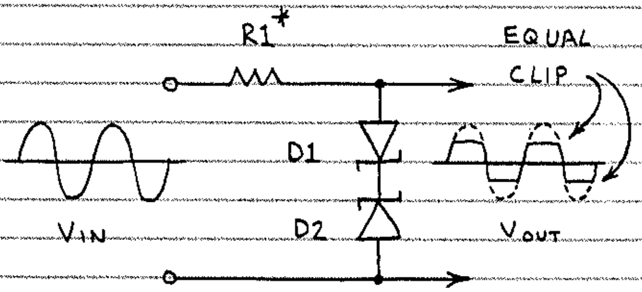


☐ WAVEFORM CLIPPER



THIS CIRCUIT IS HANDY FOR REDUCING AN INCOMING SIGNAL VOLTAGE TO A LOWER, MORE MANAGEABLE LEVEL. IT CAN ALSO CONVERT A SINE OR TRIANGLE WAVE TO AN APPROXIMATION OF A SQUARE WAVE. *R1: SEE ABOVE (LET I = 2 MA MINIMUM).

☐ DUAL WAVEFORM CLIPPER



THIS IS A SYMMETRICAL FORM OF THE ADJACENT CIRCUIT. IT CLIPS BOTH HALVES OF AN INCOMING WAVE EQUALLY (IF V_Z = D1 = D2). USE TO PROTECT SPEAKERS AND PHONES FROM EXCESSIVE SIGNAL LEVELS OR TO MAKE SQUARE WAVES.

TRANSISTOR CIRCUITS

INTEGRATED CIRCUITS RECEIVE MORE ATTENTION, BUT BOTH BIPOLAR AND FIELD-EFFECT TRANSISTORS HAVE MANY APPLICATIONS.

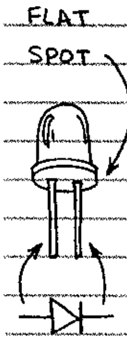
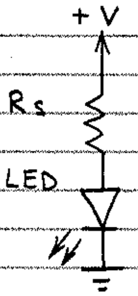
☐ LED DRIVE CIRCUIT





A SERIES RESISTOR MUST BE USED TO LIMIT CURRENT THROUGH AN LED. (EXCEPTIONS: CERTAIN PULSE CIRCUITS AND IC LED DRIVERS.)

$$R_S = \frac{+V - (V_{LED})}{I_{LED}}$$

EXAMPLE: ASSUME YOU WANT TO OPERATE A RED LED AT A FORWARD CURRENT (I_{LED}) OF 10 MA (OR 0.01 AMPERE) FROM A 5 VOLT SUPPLY. THE DATA SHEET FOR THE LED LISTS AN LED VOLTAGE (V_{LED}) OF 1.7 VOLTS. THEREFORE R_S IS (5-1.7)/.01 OR 330 OHMS.

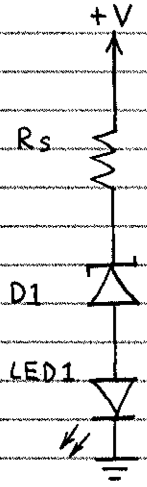
R1 AND R2 LIMIT THE CURRENT TO THE LEDs (WHICH FLASH ALTERNATELY). INCREASING THE VALUES OF C1 AND C2 WILL SLOW THE FLASH RATE.

☐ VOLTAGE LEVEL INDICATOR



IN EACH CIRCUIT THE LED(s) GLOWS WHEN V+ REACHES THE BREAKDOWN VOLTAGE (V_Z) OF ITS ZENER + V_{LED}. BE SURE TO USE INDIVIDUAL R_S FOR EACH LED. (SEE FACING PAGE.) SERVICEMAN'S GUIDE

BRAZING WORKSHOP

Individuals who desire further training in correct soldering, brazing, and welding procedures should consider attending The Harris Products Group's brazing workshop. This two-day, comprehensive course, conducted by The Harris Products Group's Technical Staff, covers fundamentals of torch brazing. The course combines classroom discussion with hands-on metal joining experience including basic metallurgy, base metals, filler metals, equipment, technique, and safety.

WHO SHOULD ATTEND?

Supervisors, foremen, quality control, service technicians, and others involved with supervision, instruction, or production of brazed assemblies should attend. Participants are encouraged to share their application problems for class discussion. For more information and course outline, contact The Harris Products Group Technical Services Department at 513.754.2000.

As a NATE®, recognized training provider, we offer several courses designed to improve your brazing skills and achieve required continuing education hours. Contact Technical Services for information.

Harris celebrates 100 years in the brazing industry. Harris is the largest manufacturer of welding, brazing and soldering consumables in the world. Our products are used in over 90 countries.

FOREWORD

Brazing is a metal joining process utilizing a filler metal that melts above 840ºF and below the melting point of the base metals. The filler metal is drawn into the joint by capillary attraction producing a sound, leak-proof connection. The above sentences briefly describe a process that is an integral part of manufacturing, installing, and repairing refrigeration and air conditioning systems. This handbook is designed to assist the serviceman or contractor in making sound brazed joints and selecting the correct filler metal for each application.

WARNING:
Protect yourself and others. Read and understand this information.
Brazing and soldering alloys and fluxes may produce FUMES AND GASES hazardous to your health.

- Before use, read and understand the manufacturer's instructions, Material Safety Data Sheets (MSDS) and your employer's safety practices.
- Keep your head out of the fumes.
- Use enough ventilation or exhaust at the flame to keep fumes and gases from your breathing zone and the general area.
- For maximum safety, be certified for and wear a respirator at all times when welding or brazing.
- Wear correct eye, ear, and body protection.
- See American National Standard Z49.1, Safety in Welding, Cutting and Allied Processes, published by the American Welding Society, 8669 NW 36 Street, #130, Miami, Florida 33166-6672;OSHA Safety and Health Standards, 29 CFR 1910, available from the U.S. Government Printing Office, Superintendent of Documents, P.O. Box 371954, Pittsburgh, PA 15250-7954.
- Material Safety Data Sheets are available for all Harris products. Each MSDS contains detailed safety and health information about possible hazards associated with use of each particular product. MSDS are available from your employer or by contacting The Harris Products Group, 4501 Quality Place, Mason, OH 45040-1971

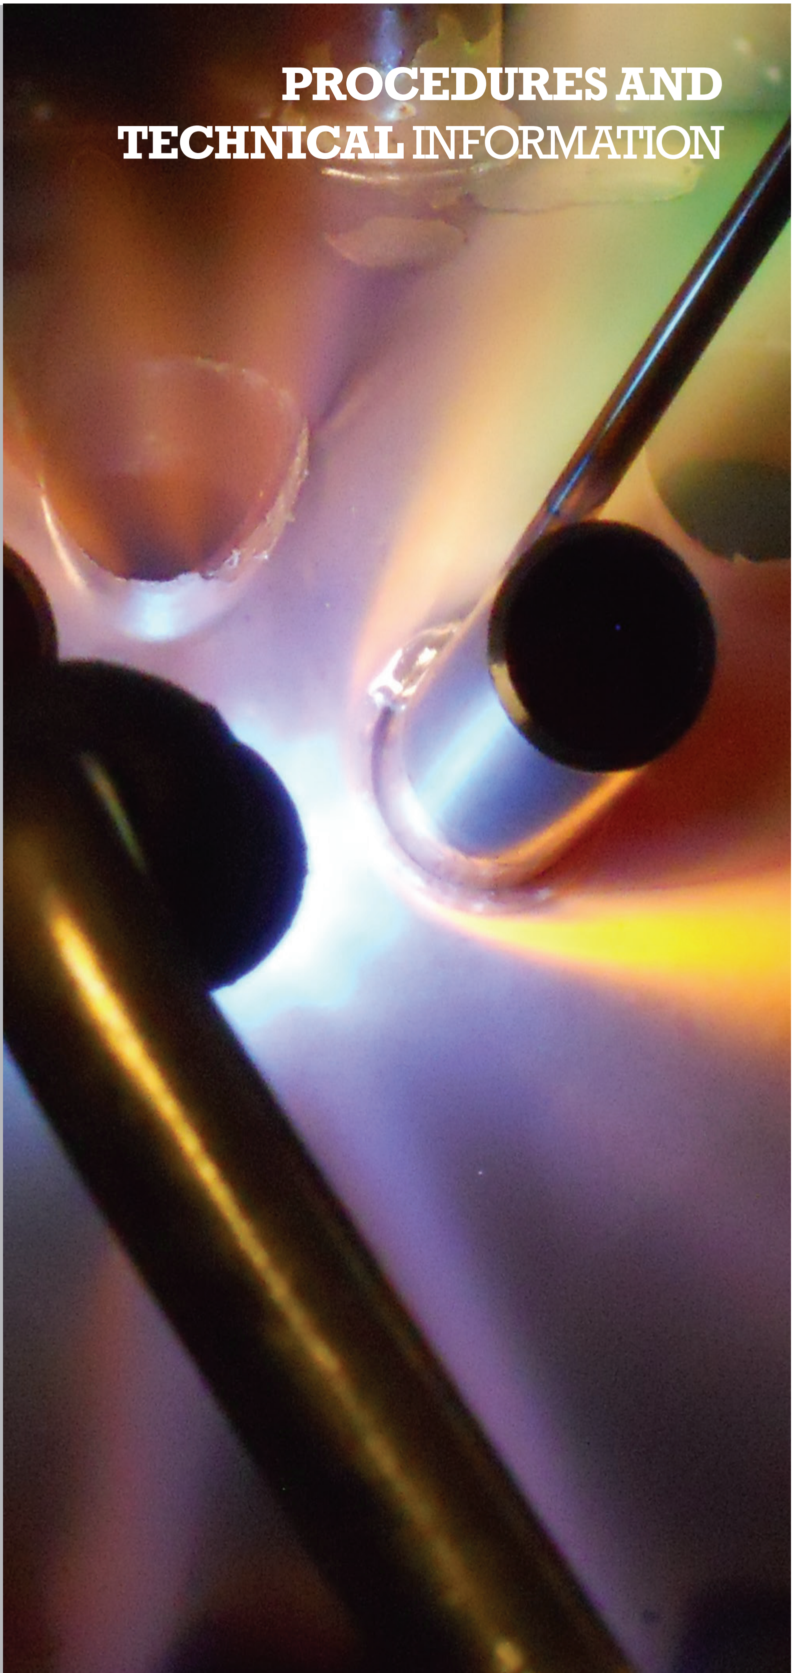
PROCEDURES AND TECHNICAL INFORMATION



CUT TUBE SQUARE.

Cut to the exact length required using a tube cutter or hacksaw. If a hacksaw is used, a sawing fixture should also be used to ensure square cuts. Remove all inside and outside burrs with a reamer, file, or other sharp edge scraping tool. If tube is out of round, it should be brought to true dimension and roundness with a sizing tool.

CLEAN TUBE END AND INSIDE SURFACE OF FITTING.

The joint surface areas should be clean and free from oil, grease, or oxide contamination. Surfaces may be properly cleaned for brazing by brushing with a stainless steel wire brush or by a stiff rubbing with emery cloth or Scotch-Brite®*. If oil or grease is present, clean with a commercial solvent. Remember to remove small foreign particles such as emery dust, by wiping with a clean dry cloth. The joint surface MUST be clean.

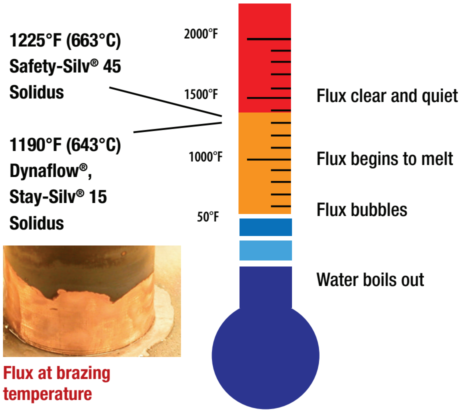
SELECT BRAZING ALLOY.

Refer to the Filler Metal Selection Chart on page 32 for recommended brazing filler metal selection. When brazing copper to copper, alloys such as Dynaflow®, Stay-Silv® 5, or Stay-Silv® 15 are recommended. These alloys contain phosphorus and are self-fluxing on copper. When brazing brass or bronze fittings, Stay-Silv® white flux is required with these alloys. When brazing iron, steel or other ferrous metals, select one of the Safety-Silv® brazing alloys such as Safety-Silv® 45 or Safety-Silv® 56 with Stay-Silv® white flux. Do not use phosphorus bearing alloys as the joint may be brittle.

*Scotch-Brite is a trademark of 3M

PERFORM PROPER FLUXING

Proper fluxing is important because the flux absorbs oxides formed during heating and promotes the flow of the filler metal. When using Stay-Silv® white flux, apply it only with a brush. To prevent excess flux residue inside refrigeration lines, apply a thin layer of flux to only the male tubing. Insert the tube into the fitting and, if possible, rotate the fitting once or twice on the tube to ensure uniform coverage.



Flux at brazing temperature

FLUX APPLICATION

White flux is used for most applications. Black flux is helpful for long heating cycles or localized heating with induction. It is also used when brazing stainless steel.

Flux goes through physical changes during heating and turns clear at about 1100°F / 593°C. This is an indication that parts are close to brazing temperature. Stir flux before use. If flux is dried out add a small amount of water until flux reaches a paste consistency.

STAY-SILV® WHITE BRAZING FLUX IS AVAILABLE IN THESE CONTAINERS:

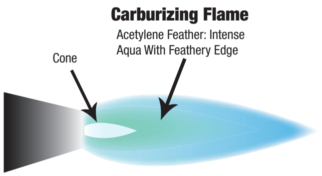
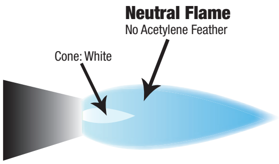
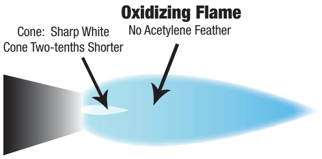
ADJUST TORCH FLAME

OXYGEN/ACETYLENE

For most brazing jobs using oxy-acetylene gases, a slightly carburizing or neutral flame should be used. The neutral flame has a well defined inner cone. Avoid an oxidizing flame.







AIR/ACETYLENE USING INFERNO® SWIRL COMBUSTION TIPS

Brazing with air/acetylene torches is a popular alternative to oxygen mixed fuel gas. The fuel gas flow aspirates air into a mixer that contains an internal vane that spins the gas to improve combustion and increase flame temperature.

If the tank has a delivery pressure gauge, set the delivery pressure to 14-15 PSI. If the tank has only a contents gauge delivery pressure is preset at the factory. Open the regulator adjusting screw all the way by turning it clockwise until it bottoms.

OPEN THE TORCH VALVE

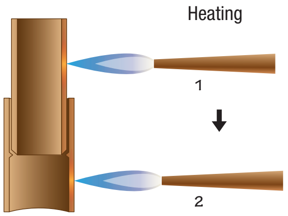
Opening the torch valve about 3/4 of a turn will provide sufficient fuel gas delivery. Do not try to meter pressure (reducing the flame) by using the torch handle valve. If a higher or lower flame is required, change to a different tip size.

OTHER FUEL GASES

Alternate fuel gases such as propane, propylene, and natural gas can be mixed with oxygen for brazing. Refer to the Harris equipment catalog or website for equipment and setting information.

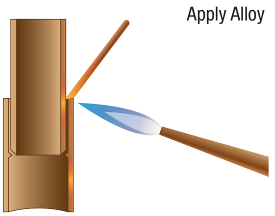
HEATING THE JOINT AREA.

Always keep the torch in short motion.

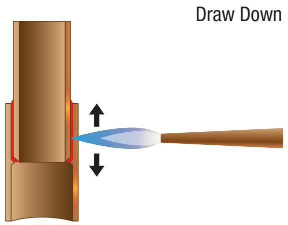


1. Start heating the tube, by first applying the flame to a point just adjacent to the fitting. Work the flame alternately around the tube and fitting until both reach brazing temperature, before applying the brazing filler metal.

2. When a flux is used, it will be a good temperature guide. Continue heating the tube until the flux passes the “bubbling” temperature range and becomes quiet, completely fluid and transparent. Watch for this on both sides of the joint to ensure even heating.



3. Direct the flame from the tube to the fitting. When alloy is applied it should quickly melt and flow into the joint.



4. Sweep the flame back and forth along the axis of the assembled joint, tube, and fitting to reach and then maintain uniform heat in both parts.

APPLY THE BRAZING ALLOY.

Feed the alloy into the joint between the tube and the fitting. Only after the base metals have been heated to brazing temperatures should the filler metal be added. At that time, the flame may be deflected momentarily to the tip of the filler metal to begin the melting process. Always keep both the fitting and the tube heated by playing the flame over the tube and the fitting as the brazing alloy is drawn into the joint. The brazing alloy will diffuse into and completely fill all joint areas. Do not continue feeding brazing alloy after the joint area is filled. Excess fillets do not improve the quality or the dependability of the braze and are a waste of material.

WHEN MAKING VERTICAL ALLOY-UP JOINTS

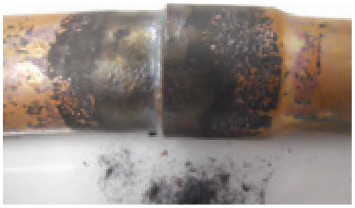
Heat the tube first, then apply heat to the fitting. It is important to bring both pieces up to temperature evenly. Keep the flame directed toward the fitting. If the tube is overheated, the brazing alloy may run down the tube rather than into the joint.

CLEAN AFTER BRAZING

All flux residue must be removed for inspection and pressure testing. Immediately after the brazing alloy has set, quench or apply a wet brush or swab to crack and remove the flux residue. Use emery cloth or a wire brush, if necessary.

TO SEPARATE A BRAZING JOINT

First clean the joint thoroughly, then flux the visible alloy and all adjacent areas of the tube and fitting. Next, heat the joint (tube and fitting) evenly, especially the flange of the fitting. When brazing alloy becomes fluid throughout the joint area, the tube can be easily removed. To re-braze the joint, clean the tube end and the inside of the fitting and proceed as directed to make a new brazed joint.

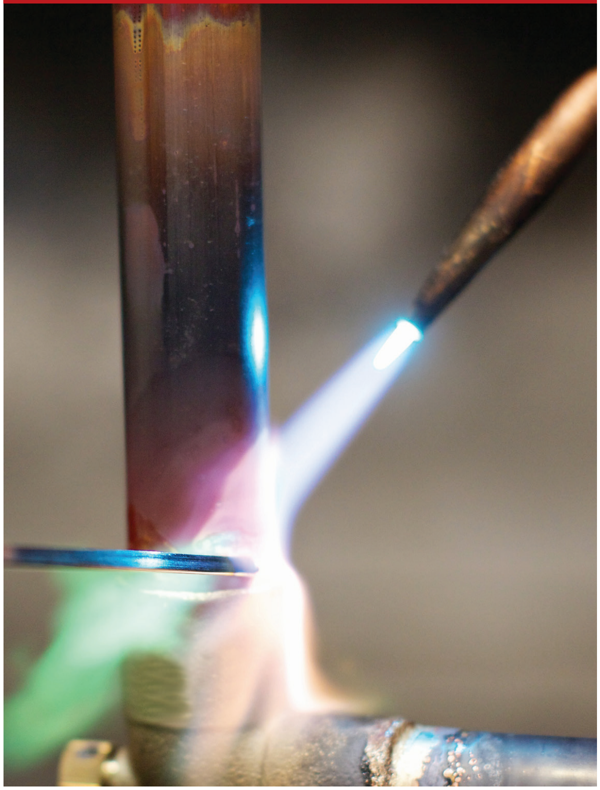


NITROGEN PURGE

During braze heating, oxide scale forms on the inside of the copper tube. These dark scales flake off and are carried by refrigerant and can potentially clog small orifices.

For HVAC/R and medical gas installations flow nitrogen through the tube during brazing to prevent internal scale formation. Use a low flow rate to avoid excess pressure inside the tube. A small hole at the line end will allow the nitrogen to escape.

BRAZING PIPE AND TUBING



The art of brazing is relatively simple, and the rules of common sense apply. Occasionally, however, things do go wrong, and the brazing process fails to do its job satisfactorily. The check lists below have been prepared to assist in such instances. They are intended to provide practical tips on what to what to look for and steps to correct them.

IF BRAZING ALLOY DOES NOT FLOW INTO THE JOINT, EVEN THOUGH IT MELTS AND FORMS A FILLET

1. The outside of the joint is hot, but the inside is not up to brazing temperature.
   Review correct heating procedure on page 9. Remember to heat the tube first to conduct heat inside the fitting.

2. There is a flux breakdown due to excessive heat. If overheated, the flux can become saturated with oxides and the brazing alloy won't flow. Try using a softer flame and/or applying a heavier coating of flux. On thick sections where heating is prolonged, or on stainless steel, Harris Stay-Silv® black flux is recommended.

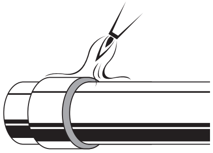
IF BRAZING ALLOY DOES NOT WET SURFACES BUT BALLS UP INSTEAD OF RUNNING INTO THE JOINT

1. Review heating techniques:
   (a) The base metals are not up to brazing temperature, and the alloy has been melted by the torch flame.
   (b) The joint has been overheated and the flux is no longer active.

2. Base metals have not been properly cleaned.

IF BRAZING ALLOY FLOWS AWAY FROM INSTEAD OF INTO THE JOINT

1. Make sure fitting is up to temperature and the flame is directed towards the fitting.



IF THE FILLER METAL CRACKS AFTER IT SOLIDIFIES

1. When brazing dissimilar metals, the different coefficient of expansion may put the filler metal in tension just below the liquidus temperature during cooling. This sometimes occurs in a copper-to-steel joint. The copper expands and contracts at a greater rate than the steel. Brazing alloys are stronger in compression, so a steel-to-copper assembly would help alleviate the problem.

2. Brazing steel (or other ferrous metals) with an alloy containing phosphorus can lead to formation of a brittle phosphide, that is prone to cracking. Braze ferrous metals with non-phosphorus content alloys.

3. Excessive joint clearance can lead to filler metals cracking under stress or vibration. Make sure clearances are held to .002" - .006" at brazing temperature (depending on alloy).

4. Too rapid quenching can sometimes cause cracking. Let joint cool more before washing off flux residue.

IF JOINT LEAKS IN SERVICE

90% of "leakers" in service are due to incorrect brazing techniques. The most common causes are:

1. Improper or uneven heating of joint. The effect of this is inadequate or incomplete penetration by the filler metal. Review proper techniques on page 9.

2. Overheating, causing volatilization of elements (phosphorus, zinc, etc.).

3. Incorrect torch flame adjustment, leading to deposition of carbon or causing excessive oxidation.

REPAIR OF LEAKS

Pinhole leaks in copper-to-copper joints brazed with phosphorus/copper or phosphorus/copper/silver filler metals can often be repaired using Blockade®. If care is taken, you can re-braze the joint with Blockade® without re-melting the original braze. Clean thoroughly before brazing.

We **DO NOT** recommend brazing over joints previously soldered with tin/lead solders. The low melting elements in the solder may prevent proper filler metal / base metal alloying.

Pinhole leaks in joints brazed with either the phosphorus or high silver alloys can usually be repaired with Stay-Brite® solder. Clean the joint thoroughly before soldering and use Stay-Clean® liquid flux.

RING OF FIRE™

STAY-SILV® 15% BRAZING RINGS

CONVENIENT | CONSISTENT | QUALITY

Ring of Fire™ is the perfect alternative to any brazing project. It's easy to use, provides a consistent braze every time and meets the same high standards expected from Harris.

THE HARRIS ADVANTAGE:

- Made in the USA.
- One of *Industry Week's* Best Plants
- Provides consistent joints
- Available in a variety of sizes
- Inventory is better managed with smaller packages
- Purchase and carry only what is needed
- Visual verification of a completed joint
- Can never use too much or too little alloy

When working in the field, reliable supplies and tools are a necessity to make the job easier. Ring of Fire™ is a great alternative to rod for any brazing project. It's easy to use and provides a consistent braze every time. It's the ring form of Harris' Stay-Silv® 15 (15% silver alloy) using the same formulation, testing and standards. Work with confidence knowing that joints are tight and leak-proof when Ring of Fire™ brazing rings are used on projects.

Ask for Harris' Ring of Fire™ brazing rings when purchasing other brazing alloys and HVAC/R supplies.

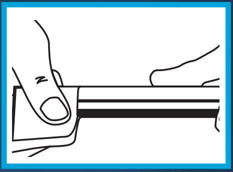
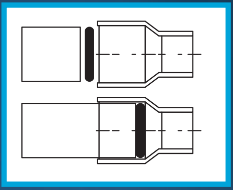
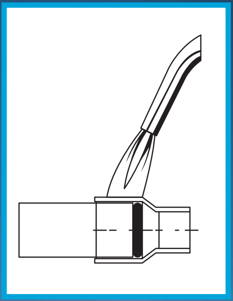
3 EASY STEPS FOR A TIGHT, LEAK- PROOF JOINT



1 Clean the tube, pipe and fittings to be brazed.



2 Place the brazing rings inside the coupling and insert the tube. Be sure the ring is at the bottom and touches the end of the tube.



3 Heat the tube and coupling, applying heat to all the parts. Heat will transfer throughout the part and draw the alloy through the capillary space. The molten braze will appear around the top of the coupling for easy visual verification of the completed braze. Read the complete instructions inside the package and refer to the Material Safety Data Sheet (MSDS) before using.

Extremely versatile, Stay-Brite® silver-bearing solders are widely used throughout the industry as a better-than-brazing method in many situations.

The important advantage of Stay-Brite® solders is the greater strength of the overall component. After joining, its lower working temperature eliminates the weakening of the base metals caused by annealment from high brazing heat. The result is a stronger, more economical joint.

Stay-Brite® silver bearing solders were introduced to the air conditioning industry more than 40 years ago.

Today, Stay-Brite® is the most used of all solders.

Stay-Brite® silver bearing solders have the same excellent affinity as Safety-Silv® alloys for bonding with most of the ferrous and nonferrous alloys (including stainless steel, nickel, copper, brass, etc.) It provides a considerably higher than necessary elongation for sound dissimilar metal joints and vibration applications. Stay-Brite® alloys range in temperature from 430°F to 535°F.

Stay-Brite® solder eliminates oxide scale formed from brazing heat. No nitrogen purge is required for HVAC/R tubes. They are cadmium free and nontoxic.

Stay-Brite® is a eutectic alloy with a single melting point of 430°F (221°C).

Stay-Brite® 8 has a solidus of 430°F (221°C) and a liquidus of 535°F (279°C). This melting range provides the ability to fill wider clearance parts.

STAY-BRITE® JOINT vs. BRAZING JOINT

Stay-Brite® offers these important advantages over silver brazing:

- Lower material costs up to 66%
- Lowers temperature up to 60%
- Speeds production up to 400%
- Faster post cleaning with little metal discoloration
- Elimination of base metal distortion
- Elimination of base metal annealment
- Elimination of oxide scale formed by heat
- Cadmium-free and nontoxic
- No internal oxide scale, so nitrogen purge is unnecessary

COMMON WIRE SOLDERS FOR TIN-LEAD

TIN-LEAD 50/50, 40/60, 60/40

Meets ASTM B32. With some exceptions, the tin-lead solders can be used to solder copper to most copper, lead, high-nickel and steel alloys.

Tin-lead solders are not recommended for use in high stress or vibration joints in the cooling industry due to lack of sufficient elongation properties. Heat sources for use with solder include soldering guns, irons, and torch applications.

TIN-ANTIMONY 95/5

Meets ASTM B32. The 95/5 tin-antimony solder is useful for applications where moderately elevated temperature is a factor. It has a higher electrical conductivity and is sometimes used where lead contamination must be avoided. The tin-antimony solders are not recommended for use on brass.

Harris 95/5 is certified to ANSI/NSF 61 and NSF/ANSI 372 for drinking water systems. Conforms to lead-free content requirements of the U.S. Safe Drinking Water Act.

FLUX SELECTION FOR TIN-LEAD, AND TIN-ANTIMONY SOLDERS

Both Stay-Clean® paste and liquid soldering fluxes are recommended, except in electrical or electronic applications that require the use of a non-corrosive flux.

BRIDGIT®

A patented, high-performance, lead-free solder developed by The Harris Products Group in response to the Federal ban on the use of lead solders in drinking water systems. This lead-free solder is specially formulated to fill both tight and loose-fitting connections. The nickel content in Bridgit® solder creates joints that are substantially stronger than those joints soldered with 50/50, 95/5 or common lead-free solders. Bridgit® has the ability to fill large gaps and "cap" joints with ease. Meets ASTM B32.

Extensive laboratory and field tests show that Bridgit® eliminates the problems associated with 95/5. Bridgit® begins to melt at 460°F, only 40° higher than 50/50. Bridgit® flux in a one pound spool provides 20% more wire than a roll of 1/8" diameter 50/50, resulting in 75 more soldered joints per roll.

Bridgit® paste flux and Bridgit® water soluble flux are certified to ANSI/NSF 61 and NSF/ANSI 372 for drinking water systems. Conforms to lead-free content requirements of the U.S. Safe Drinking Water Act. Certified to ANSI/NSF 51-Food Equipment Materials.

BRIDGIT® PASTE FLUX

Bridgit® flux is burn resistant, reducing black carbon formations that can cause leaks. This flux is unmatched for use in soldering copper, brass, bronze, galvanized, and other plumbing fittings. Works equally well with other solders.

BRIDGIT® WATER SOLUBLE FLUX

This flux is formulated so water flushing will remove flux residue from copper tube runs. Water soluble flux conforms to ASTM B813-93, and meets state and local regulations for use in potable water systems.

SAFETY-SILV®

The Harris Products Group manufactures its complete line of cadmium-free, high silver brazing alloys with the same attention to quality found in their phosphorus / copper products. Only the purest metals are used. Precision production procedures ensure consistency in product quality and performance. Safety-Silv® alloys are strongly recommended as replacements for all cadmium-bearing brazing filler metals.

SAFETY-SILV® 56

This high silver (56%) content alloy makes first-quality brazes. It is free-flowing with unequaled capillary attraction and deep penetration. Ductility is high and corrosion resistance is suitable for all but strong chemical applications. NSF 51 listed for use with food equipment materials. The silver color is an excellent match to stainless steel and silverware applications.

SAFETY-SILV®45T

Performs like a 45% silver, cadmium-bearing alloy. Lower melting temperature than Safety-Silv® 45. Excellent fillet forming qualities. Produces high-strength, ductile joints. Listed with NSF 51 listed for use with food equipment materials.

SAFETY-SILV®45

Excellent general purpose nontoxic brazing alloy. Good ductility and capillary flow. Color is silver to light yellow matches polished brass.

ESTIMATING AMOUNTS OF BRAZING ALLOYS REQUIRED

1. Locate the tube diameter to be joined and the wire size to be used. Where the row and the column intersect is the approximate length in inches of alloy required per joint.
2. Multiply the length of the alloy needed per joint by the total number of joints.
3. To convert the total length to pounds or troy ounces, divide by the inches of alloy/lb. in row A or the inches of alloy/troy oz. in row B.

HARRIS® 0

Low-cost alloy for many copper-to-copper applications where good fit-up can be maintained and brazing temperature is not critical.

STAY-SILV® 5 AND STAY-SILV® 6

Medium-range alloys, Stay-Silv® 5 is useful primarily where fit-up cannot be tightly controlled. Stay-Silv® 6 is slightly more fluid and can be used where closer tolerances are available. Both alloys are somewhat more ductile than Harris® 0.

DYNAFLOW®

Premium, medium-range silver alloy, formulated to even tighter specifications than the Stay-Silv® alloys to mirror the performance characteristics of the 15% silver brazing filler metals. Excellent for brazing both tight and poorly-fitted connections. Dynaflow's® proven reliability and acceptance by field service engineers has made it the leading choice of brazing operators.

STAY-SILV® 15

The industry standard for air conditioning and refrigeration applications. Still widely used, but now often replaced by Dynaflow® in many HVAC/R applications.

BLOCKADE®

Blockade's® unique silicon addition offers significant advantages over phos/copper and silver/phos/copper, (BCuP), brazing alloys. Among the benefits are: bright alloy color during cooling that allows visual verification of a good braze joint, improved ductility over BCuP-2 alloy, reduced brazing temperature, and reduced material costs. It is often used with Stay-Silv® white brazing flux as a replacement for high silver alloys when brazing brass.

BRAZING ALLOY WITH SILICON FOR COPPER & BRASS

Phos/copper and silver/phos/copper alloys are used to braze copper-to-copper and copper-to-brass. The phosphorus content in these alloys makes them self-fluxing on copper. When brazing brass or copper to brass, use Stay-Silv® white brazing flux. These alloys are not recommended for brazing steel or other ferrous metals.

The amount of phosphorus in the phosphorus/copper filler metals (AWS BCuP series) is the critical factor that determines the melting range of the alloys and thus, how they perform. The Harris Products Group is the brazing industry's forerunner in developing the technology to control phosphorus content. This controls alloy melting temperatures so precisely that brazing operators no longer need to make temperature adjustments from one batch of filler metals to the next. Operators know that with Harris alloys, the result will be the same with every batch, every time.

Over the decades many things have changed in the industry. However, Harris' dedication to manufacturing the world's purest and most consistent brazing alloys has not changed. Harris is committed to providing the best products every time, all the time, so all jobs are completed successfully.

THE HARRIS PRODUCTS GROUP *guarantees users a liquidus temperature variation of no more than plus or minus 6˚F, a much tighter standard than the industry requires.*

BRAZING AND SOLDERING ALUMINUM

Aluminum can be soldered or brazed if the correct procedure is followed. Pre cleaning is essential to break up the tough aluminum oxide film. Thorough brushing with a stainless steel wire brush is recommended. Most common aluminum alloys such as 1100 and 3003 can be readily soldered or brazed. It should be noted that some alloys are difficult to join. Dissimilar metal connections may be subject to galvanic corrosion in certain service conditions.

ALCOR®

Aluminum alloy with non-corrosive flux inside the wire, thus no external flux required. Very good fluidity with good capillary attraction. Post-braze cleaning unnecessary. Its low operating temperature often makes it a better choice than aluminum silicon alloys for aluminum coil repair.

AL-SOLDER®

Forms excellent corrosion-resistant joints on the tough-to-solder aluminum alloys. Joints all solderable aluminum alloys to each other and to dissimilar metals, both ferrous and non-ferrous. Also beneficial as a high-temperature solder on most other metals.

AL-BRAZE®

Superior brazing alloy for the joining of aluminum-to-aluminum. Not recommended for brazing aluminum directly to non-aluminum alloys, as the joint may become brittle. Al-Braze® is free flowing with unequaled capillary attraction, ductility and penetration. Excellent corrosion resistance.

FLUXES

DESCRIPTION	SPECIFICATION	ACTIVE TEMP	TYPICAL APPLICATION
STAY-SILV® WHITE BRAZING FLUX 7 oz., 1/4 lb., 1/2 lb.,1 lb., 5 lbs., 25 lbs., 60 lbs.	Meets Federal Spec. (OF499,Type B AWS A5.31) Class FB3-A AMS 3410	1050-1600°F (565 - 870° C)	All-purpose low temperature brazing flux used to braze most ferrous and non-ferrous metal, (exceptions are aluminum bronze, titanium, magnesium, and aluminum).
STAY-SILV® BLACK BRAZING FLUX 1 lb., .5 lbs., 5 lbs., 30 lbs., 60 lbs.	Meets Federal Spec. (OF499,Type B AWS A5.31) Class FB3-C AMS 3411	1050 -1700°F (565 - 926°C)	A boron modified formula designed for use where heating cycles are prolonged or where there is concentrated local heat as with induction brazing. Also effective in brazing stainless steel and tungsten carbide.
STAY-CLEAN® LIQUID SOLDERING FLUX 1 gl., 4 oz., 16 oz., 32 oz., 55 gl.	Meets Commercial Spec. A-A-51145 Type II Form B	300 - 700°F (148 - 371°C)	An active flux for soldering copper, brass, steel, nickel, and stainless steel. It can be used effectively with Stay-Brite® and most other solders. Remove flux residue after soldering.
STAY-CLEAN® PASTE SOLDERING FLUX 4 oz.	Meets Commercial Spec. A-A-51145 Type I Form A	300 - 600° (148 - 315°C)	Excellent flux for joining copper-to-copper and copper-to-brass. Not recommended for electrical or electronic applications.
BRIDGIT® HIGH TEMPERATURE PASTE SOLDERING FLUX 4 oz.	NSF/ANSI 61	300 – 700°F (148 - 371°C)	Designed for lead-free solders. Well suited for use in larger connections where prolonged heating will cause other fluxes to burn.
BRIDGIT® WATER SOLUBLE SOLDERING FLUX 4 oz.	ASTM B813 NSF/ANSI 61	350 - 600°F (176 - 316°C)	This flux is formulated so water flushing will remove flux residue from copper tube runs. The flux meets state and local regulations for use in potable water systems.

PHOS-COPPER BRAZING ALLOYS

DESCRIPTION	CHEMICAL COMPOSITION	SPECIFICATIONS	SOLIDUS	LIQUIDUS	TYPICAL APPLICATION
STAY-SILV® 15 	15% Ag 5% P 80% Cu	AWS A5.8 BCuP-5	1190°F 643°C	1475°F 802°C	Designed primarily for copper to copper brazing application, it may also be used in brazing brass with the use of Stay-Silv® brazing flux.
STAY-SILV® 5 	5% Ag 6% P 89% Cu	AWS A5.8 BCuP-3	1190°F 643°C	1500°F 816°C	Well suited where close fit-up cannot necessarily be maintained.
DYNAFLOW® 	6% Ag 6% P 88% Cu	--------	1190°F 643°C	1465°F 796°C	Designed for copper-to-copper applications, it may also be used on brass. Provides the ability to braze poorly fitted as well as tight connections.
HARRIS® 0 	7.2% P 92.8% Cu	AWS A5.8 BCuP-5	1310°F 710°C	1460°F 793°C	Designed for copper-to-copper. Suitable where tight tolerances can be maintained. Harris®0 has a higher solidus temperature so more heat is required, but alloy is fluid at brazing temperature.

LEAD-FREE SOLDER

DESCRIPTION	CHEMICAL COMPOSITION	SPECIFICATIONS	SOLIDUS	LIQUIDUS	TYPICAL APPLICATION
BRIDGIT® SOLDER 	-------	ASTM B32 Alloy HB NSF 61	460°F 238°C	630°F 332°C	Widely used in plumbing applications where lead-bearing solders are prohibited. Contains nickel, making joints tremendously strong. Wide plastic range makes Bridgit® an excellent alloy for large diameter fittings and ill-fitted or non-concentric pipes. Fills gaps and caps off easily and effectively.
STAY-BRITE® SOLDER 	4% Ag 96% Sn	ASTM B32 SN96 NSF 51• J-STD-006 SN96AG04A	430°F 221°C	430°F 221°C	Use for all metals with the exception of aluminum. Low temperature solder often used in residential HVAC. Flows quickly to penetrate tight clearances. Use Stay-Brite® 8 where wider gaps must be filled.
95/5 	95% Sn 5% Sb	ASTM B32 • Sb5 J-STD-006 Sn95Sb05A NSF 61	452°F 233°C	464°F 240°C	Well-suited for applications where moderately elevated temperature is a factor. Requires close part tolerance due to it's narrow melting range.

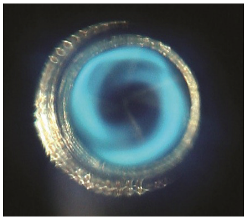
HARRIS INFERNO®

Harris Inferno® air-fuel equipment allows for soldering and brazing of a variety of tube sizes. Equipment attaches to a B (40 cu. ft.) or MC (10 cu. ft.) acetylene cylinder.

The Inferno® tip provides a special swirl combustion approach to increase flame velocity and homogenize the gas mixture.

For air-acetylene, fuel gas delivery pressure should be set at 14-15 PSI. When soldering or brazing different size connections, change tip size rather than reducing flow. The air fuel flame provides a wider heating pattern than oxy-acetylene. This is helpful in soldering or brazing larger tube diameters as heat tends to wrap around the pipe.



SWIRL COMBUSTION TECHNOLOGY

The revolutionary Inferno® tip has a specially designed insert that delivers reliable swirl combustion performance every time. The swirl combustion of the Inferno® tip is unlike anything offered on the market. Contractors get a consistent, hotter flame that will engulf and wrap around the work piece for maximum efficiency.

HARRIS PORT-A-TORCH®

The Harris Port-A-Torch® contains all the quality equipment needed for cutting, welding and brazing packaged in a rugged, molded plastic carrying case. The outfit is designed to carry one MC acetylene cylinder and one 20 cu. ft. oxygen cylinder. As supplied, the outfit is capable of cutting up to a 1” plate and welding up to a 1⁄16”plate . The outfit can cut up to a 4” plate and weld up to a 1⁄2” plate with larger tips and acetylene cylinder.

An oxy-acetylene flame produces the highest flame temperature with a more focused heat zone. Optimum delivery pressure settings for this gas mixture depends on the tip size. Refer to the tip chart for guidance.
